The Importance of
Business Owners in Assessing the Size of Precautionary Savings*

Abstract

Not properly accounting for differences between business owners and non business owners in studies of household wealth can lead to erroneous conclusions about the significance of different saving motives. Using data from the Panel Study of Income Dynamics from the 1980s and 1990s, we show that within samples of both business owners and non business owners, the amount of precautionary savings with respect to labor income risk is modest and accounts for less than ten percent of total household wealth. Previous large estimates of the size of precautionary balances resulted from pooling these two groups together. Such pooling is inappropriate given that business owners face higher labor risk and accumulate more wealth than non business owners for reasons unrelated to precautionary motives.

* We would like to thank Rob Alessie, Chris Carroll, John Cochrane, Luigi Guiso, Vincenzo Quadrini, David Romer, Paola Sapienza, Karl Scholz, Richard Thaler, James Ziliak and participants of the NBER Monetary Economics Summer Institute and seminars at the University of Chicago, the Federal Reserve Bank of Chicago, the University of Wisconsin, the Dutch Central Bank, and the University of Copenhagen for suggestions and comments. Additionally, we would like to thank Julio Rotemberg and two anonymous referees. Any errors are our responsibility. 1. **Introduction**

Precautionary saving is considered one of the most important motives to save, particularly for the young. While a variety of empirical estimates exist, several studies show that precautionary savings may contribute to as much as fifty percent of aggregate wealth for individuals under the age of fifty.\(^1\) The general approach taken in these studies is to relate measures of labor income risk faced by households to the amount of wealth households accumulate. As a result of these large empirical estimates, most models in macroeconomics now incorporate a precautionary saving motive. Moreover, the importance of precautionary saving in explaining aggregate wealth holdings has implications for public policy: The effects of welfare and taxation policies very much rely on the strength of this motive.

In this paper, we show that the large positive estimates of precautionary savings documented so far in the literature are, in fact, an artifact of pooling together two different sub-groups in the population: business owners and other households. Such mixing has the potential to confound the analysis of precautionary savings. Business owners face, on average, higher expected income risk and accumulate larger amounts of wealth than other households but for reasons *unrelated to precautionary savings*.\(^2\) The fact that business owners hold higher-than-average wealth while facing higher income risk than other households leads to a correlation between wealth and labor income risk regardless of whether or not a precautionary motive is important.

To test this hypothesis, we separately analyze precautionary saving motives of non business owners and business owners using data from the Panel Study of Income Dynamics (PSID). Within each group, our modal estimates suggest that precautionary
savings explain less than ten percent of total household wealth. Yet, when we pool these samples together, we find that as much as fifty percent of total wealth is explained by precautionary savings. Thus, estimates of precautionary savings are confounded in a sample that mixes different groups of households.

The work in this paper is the first to bridge the gap between the work of Carroll and Samwick (1997, 1998) and Kazarosian (1997), which show sizeable effects of precautionary savings, and the literature that finds small effects (Skinner (1988), Guiso, Jappelli, and Terlizzese (1992), Engen and Gruber (2001) and Lusardi (1998)). In the final portion of the paper, we discuss how the studies that find small estimates of precautionary savings have implicitly controlled for differences between non business owners and business owners either by excluding business owners from their samples or by excluding business wealth from their measure of household savings.

2. **Estimating the Size of Precautionary Balances**

Intertemporal models of consumption/saving behavior under uncertainty predict that agents accumulate wealth to insure themselves against risk (Deaton (1991), Carroll (1992, 1997)). For the most part, the precautionary saving literature has focused its attention on the relationship between labor income risk and wealth accumulation.³ All else equal, households that face more labor income risk should accumulate more wealth to insure themselves against unexpected income realizations.

Using calibrated theoretical models, several researchers have calculated that precautionary savings can explain as much as fifty percent of total wealth in the U.S. economy (Skinner (1988), Caballero (1990, 1991), Carroll (1992), and Gourinchas and
Parker (2002)). Existing empirical estimates using micro data have yielded mixed results, but studies like Carroll and Samwick’s (1997, 1998) have shown that precautionary saving is the leading motive to accumulate wealth and can explain roughly half of the total wealth of U.S. households.

A. Empirical Specification

The empirical strategy of estimating the size of precautionary balances using micro data is based on the following specification:\textsuperscript{4}

\[
\ln(W_{it}) = \alpha_0 + \alpha_1 \sigma_{it}^{\text{permy}} + \alpha_2 \sigma_{it}^{\text{transy}} + \alpha_3 \ln(y_{it}) + Z_{it} \beta + u_{it}
\]  

(1)

where $\ln(W_{it})$ is the log of a measure of household $i$’s wealth in period $t$, $\ln(y_{it})$ is the log of $i$’s permanent income in $t$, and $\sigma_{it}^{\text{permy}}$ and $\sigma_{it}^{\text{transy}}$ are, respectively, measures of the variance of permanent shocks and transitory shocks to $i$’s income. The $Z$ vector includes additional controls designed to capture potential household differences in preferences and the hump-shaped profile of wealth over the life cycle.

According to the precautionary saving model, wealth is a function not only of permanent income, but also of uninsurable income risk faced by the household. Almost all empirical studies designed to estimate the size of precautionary balances using micro data proxy uninsurable risk with either the variance of income (Carroll and Samwick (1997, 1998)), the variance of consumption (Dyman (1993)), or they exploit actual job loss or expectations of future job loss (Lusardi (1998) and Carroll, Dynan and Krane (2003)). In this paper, we follow Carroll and Samwick (1997, 1998) by using panel data to distinguish between the variance of permanent and transitory shocks to income.
B. Data

To estimate (1), we use data from the PSID. We examine accumulated household wealth in either 1984 or 1994. This broadens the analysis performed in Carroll and Samwick (1997, 1998), which only analyzed household wealth accumulation within the PSID using 1984 wealth data. The measure of wealth used is total net worth, which is defined as the sum of checking and savings accounts, bonds, stocks and mutual funds (including IRAs), home equity, other real estate, business equity, cars and other vehicles, and other assets, minus the value of all debts. Since we use logs, we exclude households who have negative or zero net worth in our sample, which amount to a little more than five percent of our sample. All dollar amounts in the paper are in 1997 dollars.

Following equation (1), we regress the log of household wealth in year \( t \) (either 1984 or 1994) on both permanent income and measures of the variance of income. We construct permanent income for each household by taking the seven-year average of non-capital income around the period for which we are measuring their wealth. Specifically, when explaining 1984 (1994) wealth holdings, we define permanent income as the average of non-capital income between the years of 1981 and 1987 (1991 and 1997). We use panel data from the PSID to compute the variances of permanent and transitory shocks to income. We follow the same procedure put forth by Carroll and Samwick (1997, 1998).

Since both permanent income and the variances of permanent and transitory income are measured with error, we instrument for these variables using a large instrument set. As suggested by Carroll and Samwick (1997, 1998), we use occupation
dummies and these dummies interacted with age and age squared, as well as industry
dummies. In addition, we use the unemployment rate in the county of residence during
the prior year, the variance in the county unemployment rate over the sample period, and
a dummy for whether the head belongs to a union.\textsuperscript{8} See Lusardi (1997, 1998) and Engen
and Gruber (2001) for the justification of using this latter set of variables as instruments
for the variance of income.\textsuperscript{9}

Table A2 in the Appendix shows our estimates of the variances of permanent and
transitory income by one-digit occupational categories. There are sizeable differences in
income variances across occupations. For example, self-employed managers are more
likely to experience a shock to both their permanent and transitory components of income
than managers employed in firms. Farmers and farm laborers are also more likely to face
a higher variance of transitory income. The estimates reported in Table A2 closely match
the estimates reported by Carroll and Samwick (1997).

When estimating (1), we also include additional controls ($Z$) to capture additional
reasons why household wealth may differ across households. The $Z$ vector includes the
following demographics: age, age squared, race, gender, marital status, and educational
attainment. In addition, we exploit the panel dimension of the PSID to control for past
income and wealth shocks experienced by households. Specifically, we include year
dummies, along with two dummies for whether the household head was unemployed
during the year when the wealth data were collected and whether they were unemployed
any time during the prior four years (1980–1983 or 1990–1993). Households that are
more likely to face high income risk are also more likely to have been hit by past
negative income shocks, and this may weaken the estimated relationship between wealth
and risk. We also include dummies for past positive shocks, such as having received inheritances or other lump-sum payments.

Lastly, similar to Carroll and Samwick, we restrict our sample to households whose head is between the ages of 26 and 50 in the year in which the wealth is measured. A detailed description of other restrictions we used in constructing our final sample is reported in the data appendix. Our final sample includes 2,144 households. Appendix Table A1 includes descriptive statistics of the main variables we use in our empirical work.

C. Rationale for Splitting Sample By Business Ownership Status

One of the problems in estimating the regression described above on a sample of the general population is that the general population pools together two distinct subgroups. Mixing together households that own a business with other households can be problematic to the extent that business owners as a group face higher risks and also accumulate larger amounts of wealth for reasons unrelated to precautionary saving. The large positive estimates of precautionary savings documented in the literature may simply be an artifact of pooling together business owners and non business owners.

Despite the addition of the $Z$ vector of controls in (1), there are at least three reasons to believe that business owners may accumulate higher amounts of wealth than their non business owner counterparts conditional on measured permanent income controls.\textsuperscript{10} First, and potentially most importantly, business owners and non business owners differ in their propensity to have a pension. Using data from the Health and Retirement Survey (HRS) we find that only 30 percent of older non-retired business
owners have a pension. The comparable number for non business owners was nearly twice as high, at just under 60 percent. This difference in pension participation is important when discussing differences in non-pension wealth holdings between business and non business owners. Holding permanent income constant, business owners may accumulate more non-pension wealth than non business owners given that they have to accumulate additional wealth to fund their consumption during retirement. Given that over this time period the PSID does not measure pension participation or pension wealth, we cannot include pension wealth in our estimation of (1).

A second concern in estimating wealth regressions on a sample that pools together business owners and non business owners (without controlling for business ownership) is that business owners and non business owners may display different preferences; for example, different bequest motives, different degrees of risk aversion, and different rate of time preferences. To the extent that business owners are more patient than non business owners, household wealth at any given point in time prior to retirement will be higher for business owners than non business owners, all else equal. Ideally, we would like to control for such differences in our Z vector. However, the PSID does not include variables that measure well household differences in preferences.

The last reason that (1) may be misspecified when regressed on a pooled sample of business owners and non business owners is that permanent income is mismeasured for business owners relative to non business owners. As mentioned above, our measure of permanent income is a simple time average of non-capital income. While non-capital income is likely to be a sufficient measure of compensation for non business owners, it has been shown to be a poor measure for business owners. There are three main reasons
that can explain this fact. First, tax evasion may drive some business owners to underreport their labor income. Second, tax avoidance drives some business owners to retain part of their compensation within the business.\textsuperscript{12} Third, tax evasion and tax avoidance aside, it is hard to specify and measure the actual labor return from business ownership; the part of business income attributed to capital and to labor is inevitably arbitrary in many cases. This is even more problematic given that the PSID imputes a large fraction of labor income for households that own a business. This type of mismeasurement is problematic for the analysis above, particularly given that the return on investment of business owners (i.e., their total compensation) is likely correlated with the underlying risk of the project.

In this respect, there is information within the PSID to address this problem. As a potentially better proxy for household permanent income, in some of our specification we use average household consumption in lieu of average household non-capital income in the estimation of \textsuperscript{(1)}.\textsuperscript{13} According to standard specifications of the Permanent Income Hypothesis, consumption in year \( t \) is a sufficient statistic for the household’s period \( t \) expectation of lifetime resources. The PSID provides information on food consumption at home (including food stamps) and food outside the home. Although the sum of these two measures is only a limited proxy for total nondurable consumption, many studies have used food consumption to test the predictions of the theory and have found that food consumption often displays characteristics similar to non-durable consumption (Lusardi (1996), Hurst (2004)). We take the average of the sum of food at home, food away from home, and food stamps over the sample period as a proxy for permanent income to test the sensitivity of the model to our original definition of permanent income. We
instrument for the variances of income and average food consumption using the same set of variables as before.

With these concerns in mind, we estimate a variety of different specifications to address the potential problems of pooling together non-business owners and business owners when estimating (1). In particular, in some of our specifications we use the average of food expenditure as our measure of non-capital income. As described above, this will allow us to assess the importance of the mismeasurement of permanent income of business owners. Also, to explore the robustness of our results, in some of our estimations, we change the dependent variable in (1) to be the log of total net worth less business equity. The reason for this is that it is likely that business wealth is correlated with the underlying riskiness of the business. If equity in private businesses is illiquid, the returns on risky business ownership may show up in higher business wealth. Moreover, it seems implausible that business owners would hold their precautionary wealth in their businesses; income streams from the business and the value of the business are clearly positively correlated. For savings to provide insurance, we expect business owners to hold at least a portion of their precautionary reserves outside of their businesses.

3. Data and Pooled Estimates

Empirical estimates of our baseline specification of equation (1) for the pooled sample are reported in Table 1. For brevity, only the coefficient estimates of the variances are reported. Both estimates of the income variances are statistically significant and show that, as predicted by the theory, higher income risk leads to higher wealth holdings. Most
relevant for our work is that, according to these estimates, the precautionary saving motive is very important.

We perform two experiments to provide context to the magnitude of the coefficient estimates. First, we move households from an occupation with low income risk (professionals, with an estimated variance of permanent income shocks of 0.013 and an estimated variance of transitory shocks of 0.040) to an occupation with high income risk (operatives and laborers, with an estimated variance of permanent shocks of 0.0199 and an estimated variance of transitory shocks of 0.059). The movement across those occupational categories increases household wealth by thirty-four percent (all else equal). If we move a manager who is employed by a firm (estimated permanent and transitory variances equaling 0.017 and 0.030, respectively) to being a self-employed manager (estimated permanent and transitory variances equaling 0.027 and 0.0866), we predict that household’s wealth would increase by fifty-three percent.

As a second way to gauge the magnitudes of the coefficients in Table 1, we compute the total amount of aggregate wealth explained by precautionary savings by eliminating all income risk, i.e., setting both variances to zero. After doing so, we can calculate how much wealth households would accumulate when facing no income risk and compare that amount to the estimates when income risk exists. As reported in Table 1, we find that more than forty-seven percent of household wealth can be explained by precautionary motives. Ninety-five percent bootstrapped confidence bands around our estimate suggest that the share of total wealth explained by precautionary savings ranges from about forty-one to sixty percent. Thus, our estimates are consistent with the existing literature (Carroll and Samwick (1997, 1998)).
Our hypothesis is that the large empirical estimates of the importance of precautionary savings documented in the first column of Table 1 (and from much of the existing literature on precautionary savings) result from pooling together business owners and non-business owners. In column 2 of Table 1, we show the results of our estimation of (1) on a sample that only includes households that do not own a business. Otherwise, the sample and specification are exactly the same as the one used for the estimates presented in column 1 of Table 1.

The first thing to note is that among non-business owners the estimates on both income variance measures fall dramatically in magnitude and are no longer statistically different from zero. To gauge the overall size of precautionary balances within this sample, we repeat the experiments above. First, we suppose that households move from an occupation with low income risk (professionals) to an occupation with high income risk (operatives and laborers). Under this experiment, household wealth would barely change at all. Second, we assume households face zero or very low risk and examine how much of the total wealth held by non-business owners is explained by precautionary savings (as in the procedure described previously). The estimation implies that precautionary savings explain \(-4.1\) percent of total wealth holdings when setting the variances to zero and \(-1.4\) percent when setting the variances to the lowest mean value. Note that these estimates are not statistically different from zero. The bootstrapped 95 percent confidence bands for the first estimate (zero variances) are minus forty percent to twelve percent and for the second estimate (lowest mean value) are minus nine to seven percent. In other words, the confidence bands from these estimates imply that at most twelve percent of total wealth held by households under the age of fifty is explained by
precautionary savings. The result of this specification is striking. It says that among non-business owners (about eighty-five percent of the population) there is, at best, only a small systematic relationship between labor income risk and household wealth holdings.\(^{16}\)

Another set of variations serves to emphasize just how critically the estimated size of the precautionary saving motive hinges on the inclusion of business owners in the sample used for the estimation. One might argue that because business owners are, on average, wealthier than other households, the estimates may simply capture different behavior among the wealthy. To assess whether we are simply measuring wealthy or successful households when considering business owners, we cut the data in two additional ways. First, we remove from our sample those households in the top twenty percent of the income distribution (leaving us with 1,716 observations). Second, we exclude from the sample households who own stocks (for a sample of 1,238 observations). In both cases, we find that precautionary savings continue to explain a large (and statistically significant) portion of total household wealth. Specifically, for the sample of households in the bottom eighty percent of the income distribution, forty percent of wealth appears to be explained by precautionary motives. In the sample of non-stock owners, thirty-five percent of wealth appears to be explained by precautionary motives. Thus, in both cases substantial fractions of wealth can be explained by the precautionary motive, arguably because each sample includes a substantial fraction of business owners; eighteen percent of households in the bottom eighty percent of the income distribution and seventeen percent of non-stock owners report owning a business.
The results in column 2 of Table 1 do not imply that precautionary savings are not important in explaining aggregate wealth within the United States. It may be that business owners respond strongly to labor income risk. Their response to such risk, in turn, may give rise to large amounts of wealth in the economy, a point previously noted in the work by Carroll and Samwick (1997, 1998). In fact, a key contribution of this paper is to show that even among the sub-sample of business owners, the relationship between wealth and income risk proxies for something other than precautionary motives.

To probe the precautionary motives of business owners further, we reestimate (1) for this group alone. The results of this estimation are shown in column 3 of Table 1. The coefficients on both variance measures are positive and the coefficient on the variance of the permanent income shock is statistically different from zero. Using the same procedure as above and setting the variances to zero, we find that only twenty-three percent of wealth among business owners can be explained by precautionary motives. These effects are also statistically different from the non-business owner sample. Notice that even within the business owner sample, the estimated importance of precautionary savings in explaining aggregate wealth holdings is much lower than the Carroll and Samwick estimates. Within both the samples of business owners and non-business owners, the importance of precautionary savings in explaining aggregate wealth accumulation is much smaller than what the pooled estimates imply. At a minimum, the pooled estimates overstate the size of the precautionary motive, reflecting the fact that business owners face more labor income risk and are more likely to accumulate wealth for non-precautionary reasons.
In columns 4 and 5 of Table 1, we make two modifications to the specification presented in column 3. In column 4, we replace the dependent variable with the log of total net worth less business equity. While wealth is fungible and business owners may face tax and other incentives to keep as much as possible in the business, it is unlikely that they hold their precautionary wealth exclusively in business equity, particularly in light of the fact that business equity is highly correlated with negative shocks to business income. Under this specification, the estimated impact of the precautionary saving motive falls by more than half (from twenty-three percent to close to eleven percent when setting the variances to zero). Excluding business equity from our measure of total wealth, non-business wealth response to risk is now fairly small among business owners.

Using the log of non-business wealth as our dependent variable and replacing average food consumption as our proxy for permanent income (an important modification for the sample of business owners), we now find that precautionary motives explain only a little more than six percent of total wealth within the sample of business owners. The ninety-five percent confidence bands on these estimates range from roughly negative three percent to twelve percent.

Given how different business owners are, we return to the pooled sample and reestimate (1), directly controlling for a business ownership dummy and the business ownership dummy interacted with the two variance measures. These results are shown in columns 1–3 of Table 2. Column 1 is our baseline specification where the dependent variable is the log of total net worth and the control for permanent income is average non-capital income. In column 2, the dependent variable is the log of net worth less business equity and the control for permanent income is average of non-capital income. In column
3, the dependent variable is the log of net worth less business equity and the control for permanent income is average food expenditure. These results show that once we account for a business ownership dummy (and business ownership interacted with the variance measures), the percentage of wealth explained by precautionary savings for labor income risk is very small, even in the pooled sample. The estimated percentage of wealth explained by precautionary motives in these specifications ranges from minus ten percent to thirteen percent. The confidence bands strongly reject the estimates from the pooled sample in Table 1, column 1, which did not control directly for business ownership.

In columns 4 and 5 of Table 2, we show that even if we do not directly control for business owners but instead omit business wealth from our measure of wealth and use average food expenditure for our measure of permanent income, the implied share of aggregate wealth explained by precautionary motives decreases from forty-seven percent to no greater than seventeen percent.\(^\text{18}\)

4. Conclusion

Some of the papers in the literature on precautionary savings report that precautionary motives explain about half of total wealth, while other papers suggest a much smaller fraction. The results of this paper show that the high estimates of the size of precautionary balances are driven by mixing two very different groups of households: business owners and non business owners. Relative to the latter group, the former holds large amounts of wealth for non-precautionary reasons and also faces high income risk. Although pooling these two groups leads to very large estimates of the share of
precautionary wealth out of total net worth, we show that within these two groups separately, the estimated amount of precautionary savings is low.

Our results can explain and reconcile the widely different estimates of precautionary savings that are found using different micro-data sets. For example, Engen and Gruber (2001), Hrung (2000), Lusardi (1998), and Skinner (1988) all found rather modest estimates of the importance of precautionary savings. Upon examination, these findings are consistent with our results. For example, in their estimation of precautionary savings, Engen and Gruber (2001) use data from the Survey of Income and Program Participation and consider a measure of gross financial assets that does not include business equity. Similarly, Hrung (2000) uses a measure of liquid financial wealth from the Continuous Work History Sample Panel of the U.S. Treasury that excludes business equity. Lusardi (1998) uses total net worth in her estimation, but her sample excludes the self-employed. All of these papers—which found low estimates of the importance of precautionary savings in explaining wealth holdings within the U.S. economy—have either explicitly or implicitly controlled for differences between business owners and non-business owners.

Lastly, we want to stress that the results presented in this paper have implications for research well beyond precautionary savings. We show that when examining household consumption or saving behavior, it is important to account for the differences between business owners and non-business owners. This is likely to be equally important in studies assessing the importance of bequest motives, since business owners are more likely to leave bequests to their children. Similarly, business owners may play a critical role in assessing the offset of pension and private wealth; business owners are far less
likely to have pensions than other households but may hold large amounts of wealth for reasons unrelated to pensions. We conclude that, given the well-documented differences between business and non business owners, micro studies of household consumption and saving decisions should attempt to account for these differences. Alternatively, researchers should exclude business owners from their samples.

Notes: This table reports Instrumental Variables (IV) estimation of a regression of the log of net worth on the variance of permanent income shocks, the variance of transitory income shocks, and permanent income. The regression also includes controls for household demographics and past shocks to wealth. See text for full detail of additional variables included. Estimation was performed using PSID wealth data from 1984 and 1994. Sample was restricted to households between the ages of 26 and 50. Permanent income is measured as average household non-capital income. The two variance measures as well as permanent income were instrumented using
occupation dummies, industry dummies, interactions between occupation dummies with age and age squared, union status of household head, the county unemployment rate, and the variance of county unemployment rate. Sample pools together business owners and non business owners. We compute the percentage of net worth explained by precautionary savings by predicting net worth using the regression equation for each household. We then predict the household’s net worth using the regression equation for each household but this time setting permanent and transitory variances to zero. We compute the percentage of net worth explained by precautionary saving by comparing these two predicted values. See text for full details. Robust standard errors reported in parentheses.

DATA APPENDIX

PANEL STUDY OF INCOME DYNAMICS (PSID)

A.1 Sample selection

We use data from the PSID in 1981–87 and 1991–97. To construct our final sample, we drop all households from the Survey of Economic Opportunity (SEO), which over-samples the poor, and we drop the Latino sub-sample. We also drop households with heads who were younger than 26 or older than 50 in 1981 (for the 1981–1987 panel) or 1991 (for the 1991–1997 panel). We drop households with invalid education, occupation, or industry responses (including the unemployed and those who are not participating in the labor market) in those same years, as well as households where the marital status of the head changes at any time during the period considered. We also drop households from the sample if the head or the wife changes during the period considered. Finally, to avoid the estimation of the permanent and transitory variances being driven by a few households with extremely volatile incomes, we drop households whose income in any year falls below twenty percent of the average household income during the time period. We also exclude observations with missing county unemployment rates. When using log wealth over permanent income, we also exclude those observations with zero or negative net worth. In total, the number of households dropped due to missing observations or excessively volatile income was small.

A.2. Definitions

Net worth
Net worth is defined as the sum of all assets owned by the household at the time of the interview. It includes money in checking or savings accounts and in IRAs, money market bonds, Treasury bills, bond funds, cash value in life insurance policies, valuable collections for investment purposes, rights in trusts or estates, shares of stock in publicly held corporations, mutual funds, investment trusts, stocks in IRAs, value of all vehicles; and value of all (partially or fully) owned farms and businesses. The value of all those assets is net of anything owed on them, such as the value of mortgages and due payments of car loans. Other debts that have been subtracted include mortgages on other owned real estate, credit card charges, student loans, medical or legal bills, and loans from relatives.

Non-capital current income

We calculate non-capital income as labor income plus transfers of the head, spouse, and all other members of the household. Labor income includes wages and salaries, overtime compensation, bonuses, commissions and tips, and income from the practice of a profession or trade, as well as the labor share of income from farm income and business income. Total transfers include (a) ADC/AFDC, Supplemental Security income and other welfare transfers; (b) Social Security transfers; (c) other retirement income, pensions, and annuities; (d) unemployment compensation; (e) workers’ compensation; (f) child support transfers; (g) transfers from relatives and friends; and (h) food stamps, which are not included in any of the transfers above. All dollar values were deflated to 1997 dollars, using the CPI.

Permanent income
We consider two alternative definitions of permanent income. The first one is simply the time average of current income. For example, for a given household in the 1981–1987 panel, permanent income is average income over that period. We have also considered the time average of expenditures on food (the sum of food at home, food away from home, and annual value of food stamps) over the same period as a proxy for permanent income.

**Business owner**

A household is classified as business owner if answering ‘yes’ to the following question in the wealth supplement of the PSID: ‘Do you (or anyone in your family living there) own part or all of a farm or business?’ Our alternative definition of business owner is the household whose head is self-employed. The exact wording of that question is ‘Do you (head) work for someone else, yourself, or what?’ The possible answers to this question are (1) someone else; (2) both someone else and self; and (3) self only. A household is considered self-employed if the answer is either (2) or (3).

**A.3 Construction of the variance of permanent and transitory incomes**

To calculate the variance of permanent and transitory income, we follow closely the method used by Carroll and Samwick (1997). We assume that the natural logarithm of current non-capital income, $y_t$, can be decomposed into three components:

\[ y_t = g_t + y_t^p + \varepsilon_t \]  \hspace{1cm} (A.1)

where $g_t$ represents a predictable trend due to demographic and human capital factors, $y_t^p$ is the permanent component of income, and $\varepsilon_t$ is the transitory component.
The transitory component is a white noise with variance $\sigma^2_\varepsilon$, whereas the permanent component follows a random walk:

$$y_t^p = y_{t-1}^p + \eta_t$$  \hspace{1cm} (A.2)

where $\eta_t$, another white noise with variance $\sigma^2_\eta$, is the shock to permanent income in period $t$; $\varepsilon$ and $\eta_t$ are assumed to be uncorrelated at all leads and lags.

The first step in the construction of the variances consists of removing the trend. To do that, we run a cross-sectional OLS regression of the natural logarithm of current income on age; age squared; a gender dummy; a marital status dummy; a white race dummy; education, occupation, and industry dummies; and the interaction of the education and occupation dummies with age and age squared. The residual from that regression is our detrended income, $\hat{y}_t$.

Next, we calculate the $d$-year difference of detrended income, $r_d$:

$$r_d \equiv \hat{y}_{t+d} - \hat{y}_t$$ \hspace{1cm} (A.3)

Combining (A.3) with equations (A.1) and (A.2), and ignoring the trend $g_t$, since it has been previously removed,

$$r_d = \sum_{s=1}^d \eta_{t+s} + \varepsilon_{t+d} - \varepsilon_t$$ \hspace{1cm} (A.4)

$r_d^2$ is the estimate of the variance of $r_d$, and it is related to the variance of the permanent and transitory components of income, since, using (A.4) we find that

$$r_d^2 = \text{Var}(r_d) = d\sigma^2_\eta + 2\sigma^2_\varepsilon$$  \hspace{1cm} (A.5)

In principle, (A.5) alone would be enough to calculate the variances. However, we exploit all the information contained in the data set by running an OLS regression,
household by household, of $r_d^2$ on $d$ and a constant. The coefficient on $d$ is our estimate of the permanent variance of income, whereas the constant (divided by two) is our estimate of the transitory variance of income.

Note: Sample includes households in either the 1984 or the 1994 PSID between the ages of 26 and 50. See data appendix for additional sample restrictions. Average household non-capital income is the average of household non-capital income between 1981 and 1987 for households from the 1984 PSID and between 1991 and 1997 for households from the 1994 PSID. Non-capital income includes all income from wages and transfers received by the household. All dollar amounts are in 1997 dollars.

Endnotes

1 For a review of early work on precautionary savings, see Deaton (1992) and Browning and Lusardi (1996). For more recent results, see Carroll and Samwick (1997, 1998), and Carroll, Dynan, and Krane (2003).

2 See Hurst and Lusardi (2008) for a discussion of some of the reasons business owners hold more wealth than non-business owners with a similar lifetime trajectory of labor income. Below, we discuss some of these reasons in detail.

3 Labor income risk is only one of the risks faced by households. Other risks include, for example, health and longevity. As with the bulk of the empirical work on precautionary savings, the focus in this paper is on examining the relationship between non-capital income risk and household wealth accumulation. Given that our attention will be on heads of households aged 26–50, and labor accounts for most non-capital income, labor income risk is likely to be the most important risk these households face.

4 This specification is the one used by Carroll and Samwick (1997, 1998) and is similar to specifications used by Kazarosian (1997), Lusardi (1998), and Carroll, Dynan, and Krane (2003).

5 While the distribution of wealth is very skewed to the right and we need to worry about the influence of very rich households, using the log transformation has some shortcomings. First, high-risk households may get hit by shocks that deplete their resources and push them into negative wealth. In this case, the selection of the sample can bias our estimates. Second, it could be that the precautionary saving motive prevents households from going heavily into debt, but they still would not hold positive wealth. In
other words, the precautionary saving motive may simply limit the amount of borrowing that a household would otherwise undertake. Since we eliminate the households in debt, we may end up incorrectly calculating the amount of precautionary savings undertaken in the economy. To potentially overcome that problem, we have used the ratio of wealth over permanent income as our dependent variable and retain the observations with zero or negative net worth in the sample. Our main results are unchanged. See Hurst, Lusardi, Kennickell and Torralba (2005), Table 2.

6 See the data appendix for details on how non-capital income is defined.

7 See the data appendix for a detailed summary of how we computed the income variances.

8 These instruments have been criticized by Lusardi (1997) and Fuchs-Schündeln and Schündeln (2005). We discuss estimates using a different set of instruments later in the text.

9 The predictive power of the instruments is not very high. The F-statistic in the first-stage regression for the variances of income was just above 2. We choose this instrument set to maintain comparability with the instrument set used by Carroll and Samwick. However, in a robustness appendix (posted on the web page of Erik Hurst and Annamaria Lusardi), we use a different instrument set that has significantly higher predictive power. The conclusions of this paper are unchanged with that instrument set. The pooled sample of business owners and non business owners lead to high estimates of the impact of precautionary savings on household wealth accumulation. However, after controlling for business owners, the empirical importance of precautionary savings falls precipitously.

10 See, also, Hurst and Lusardi (2008).

12 There is ample evidence that suggests that business owners are much more likely to underreport their income relative to non business owners. For example, see Engstrom and Holmund (2006). The use of food expenditure to test for underreporting of income by business owners is also common in this literature. Again, see Engstrom and Holmund (2006). Pissarides and Weber (1989) also show that food consumption can be used to gauge underreporting of income with more general populations.

13 See, among others, Meyer and Sullivan (2003), who also use food consumption as a proxy for permanent income. Likewise, Aguiar and Hurst (2005) show that food expenditures are good predictors of a household’s permanent income.

14 To do this, we use the estimates from (1) to predict log wealth for each household. We then predict log wealth for each household setting the variances of permanent and transitory incomes to zero. To get the estimated percent of wealth explained by precautionary savings, we take the difference between the predicted log wealth with and without the variances set to zero for each household and then average over all households. We also repeat this procedure setting the value of the variances to the minimum mean value across occupations rather than setting the value to zero.

15 As long as the thought experiment entails moving a household from an occupation with high income risk to one of low income risk, general equilibrium effects can safely be ignored. However, computing the size of precautionary savings by setting everyone’s income variance to zero will likely have general equilibrium consequences. Interest rates will likely increase in an economy with no labor income risk. Higher interest rates will
induce higher saving (if the substitution effect dominates the income effect), potentially mitigating the drop in wealth accumulation. We chose to focus on the partial equilibrium magnitudes to be consistent with the thought experiments found in the earlier literature (e.g. Carroll and Samwick 1997, 1998). A general equilibrium analysis, however, is only likely to reinforce one of our main conclusions that the estimated importance of precautionary savings found in earlier papers is artificially high.

16 We obtain very similar results when we use the self-employed rather than the business owners. See the robustness appendix posted on Erik Hurst and Annamaria Lusardi’s web site. See also the discussion in Hurst, Lusardi, Kennickell and Torralba (2005).

17 Carroll and Samwick (1998) note that when they exclude farmers and the self-employed from their sample, their estimates suggest that precautionary motives explain essentially zero percent of aggregate wealth holdings. They state, “Our preferred interpretation of these findings is of course that the farmers and the self-employed provide exactly the same kind of variation in the independent variable that is very valuable to identify the coefficient on uncertainty, and hence, these groups should remain in the sample” (page 415). In fact our paper shows that business owners have high wealth (compared to non business owners) for reasons other than precautionary motives.

18 In the appendix posted on Hurst and Lusardi’s web page, we have performed a variety of robustness checks on our specifications. Among the most important, we explore the robustness of our results to alternate instrument sets. The instrument set used by Carroll and Samwick is relatively weak (i.e., the first-stage F-statistics for the instrument set are around 2). In the results shown in Tables 1 and 2, we used a similar set of instruments as Carroll and Samwick to make our results as comparable to theirs as possible. However,
we are fully aware of the problems associated with weak instruments. So, in the accompanying appendix, we used a slightly different specification (including only the total variance of income as opposed to the total variance decomposed into the permanent and transitory component) and a different instrument set. The first-stage predictive power of the instrument set in this specification increased substantially (to around standard acceptable levels of significance). The conclusions of the paper with this alternate instrument set are unchanged. The key results from the appendix are that our results are extremely robust to alternate specifications including the more powerful instrument sets, non-linear income controls, endogenous choice of occupation (as discussed in Lusardi (1997) and Fuchs-Schündeln and Schündeln (2005)), and alternate definitions of business ownership. In all cases, pooling together business and non business owners artificially increases the estimated impact of precautionary saving in explaining aggregate wealth accumulation.

19 Our procedure is, thus, not affected if the stochastic process for transitory income is a moving average of order 1 or 2. See Carroll and Samwick (1997) for more detail.
