We develop new evidence on the cumulative earnings losses associated with job displacement, drawing on longitudinal Social Security records from 1974 to 2008. In present-value terms, men lose an average of 1.4 years of predisplacement earnings if displaced in mass-layoff events that occur when the national unemployment rate is below 6 percent. They lose a staggering 2.8 years of predisplacement earnings if displaced when the unemployment rate exceeds 8 percent. These results reflect discounting at a 5 percent annual rate over 20 years after displacement. We also document large cyclical movements in the incidence of job loss and job displacement and present evidence on how worker anxieties about job loss, wage cuts, and job opportunities respond to contemporaneous economic conditions. Finally, we confront leading models of unemployment fluctuations with evidence on the present-value earnings losses associated with job displacement. The model of Mortensen and Pissarides (1994), extended to include search on the job, generates present-value losses only one-fourth as large as observed losses. Moreover, present-value losses in the model vary little with aggregate conditions at the time of displacement, unlike the pattern in the data.

Major economic downturns bring large increases in permanent layoffs among workers with long tenure on the job. We refer to this type of job loss event as a displacement. Previous research shows that job displacements lead to large and persistent earnings losses for the affected workers.1 The available evidence also indicates that job displacement

leads to less stability in earnings and employment, worse health outcomes, higher mortality, lower educational achievement by the children of displaced workers, and other unwelcome consequences.\footnote{We review the evidence and provide citations to the relevant literature in section III. See also von Wachter (2010).}

We develop new evidence on the cumulative earnings losses associated with job displacement and the role of labor market conditions at the time of displacement. In present-value terms, men lose an average of 1.4 years of predisplacement earnings if displaced in mass-merger events that occur when the national unemployment rate is below 6 percent. They lose a staggering 2.8 years of predisplacement earnings if displaced when the unemployment rate exceeds 8 percent. These results reflect discounting at a 5 percent annual rate over 20 years after displacement. We also document large cyclical movements in the incidence of job loss and job displacement, and we investigate how worker anxieties about job loss, wage cuts, and other labor market prospects respond to contemporaneous economic conditions. Finally, we confront leading models of unemployment fluctuations in the tradition of work by Peter Diamond, Dale Mortensen and Christopher Pissarides with evidence on the present-value earnings losses associated with job displacement.

Our study builds on three major areas of research: empirical work on cyclical fluctuations in job destruction, job loss, and unemployment; empirical work on earnings losses and other outcomes associated with job displacement; and theoretical work on search-and-matching models of unemployment fluctuations along the lines of Mortensen and Pissarides (1994). In terms of a broad effort to bring together these areas of research, the closest antecedent to our study is that by Robert Hall (1995). In terms of its effort to confront equilibrium search-and-matching models with evidence on the earnings losses associated with job displacement, the closest prior work is that by Wouter Den Haan, Garey Ramey, and Joel Watson (2000).

Our empirical investigation of the earnings losses associated with job displacement draws heavily on recent research by von Wachter, Jae Song, and Joyce Manchester (2011). They develop new evidence on the short- and long-term earnings effects of job loss using longitudinal Social Security records covering more than 30 years. Our first main contribution is to characterize, drawing on their estimated empirical models, how present-value earnings losses due to job displacement vary with business cycle
conditions at the time of displacement. For men with 3 or more years of job tenure who lose jobs in mass-layoff events at larger firms, job displacement reduces the present value of future earnings by 12 percent in an average year. The present-value losses are high in all years, but they rise steeply with the unemployment rate in the year of displacement. Present-value losses for displacements that occur in recessions are nearly twice as large as for displacements in expansions. The entire future path of earnings losses is much higher for displacements that occur in recessions. In short, the present-value earnings losses associated with job displacement are very large, and they are highly sensitive to labor market conditions at the time of displacement.

Drawing on data from the General Social Survey of the National Opinion Research Center and from Gallup polling, we also examine the relationship of anxieties about job loss, wage cuts, ease of job finding, and other labor market prospects to actual labor market conditions. The available evidence indicates that cyclical fluctuations in worker perceptions and anxieties track actual labor market conditions rather closely, and that they respond quickly to deteriorations in the economic outlook. The Gallup data, in particular, show a tremendous increase in worker anxieties about labor market prospects after the peak of the financial crisis in 2008 and 2009. They also show a recent return to the same high levels of anxiety. These data suggest that fears about job loss and other negative labor market outcomes are themselves a significant and costly aspect of economic downturns for a broad segment of the population. These findings also imply that workers are well aware of and concerned about the costly nature of job loss, especially in recessions.

Our second main contribution is to analyze whether leading theoretical models of unemployment fluctuations can account for our evidence on the magnitude and cyclicality of present-value earnings losses associated with job displacement. Following Hall and Paul Milgrom (2008), we consider three variants of the basic Mortensen-Pissarides model analyzed by Robert Shimer (2005) and many others. We also consider a richer model by Simon Burgess and Hélène Turon (2010) that introduces search on the job and replacement hiring into the model of Mortensen and Pissarides (1994). The richer model generates worker flows apart from job flows, heterogeneity in productivity and match surplus values, and recessionary spikes in job destruction, job loss, and unemployment inflows of the sort we see in the data.

The search-and-matching models we consider do not account for our evidence on the present-value earnings losses associated with job displacement.
The empirical losses are an order of magnitude larger than those implied by basic versions of the Mortensen-Pissarides model. Wage rigidity of the form considered by Hall and Milgrom (2008) greatly improves the model’s ability to explain aggregate unemployment fluctuations, but it does not bring the model closer to evidence on the earnings losses associated with displacement. The model of Burgess and Turon (2010) generates larger present-value losses, because most job-losing workers in the model do not immediately recover predisplacement wage levels upon reemployment. Instead, unemployed persons tend to flow into jobs on the lower rungs of the wage distribution and move up the distribution over time. Yet when calibrated for consistency with U.S. unemployment flows, the model of Burgess and Turon yields present-value earnings losses due to job loss less than one-fourth as large as the empirical losses. Moreover, present-value losses in the model vary little with aggregate conditions at the time of displacement, unlike the pattern in the data.

Present-value income (as opposed to earnings) losses associated with job loss are even smaller in the search models we consider. Indeed, a fundamental weakness of these models is their implication that job loss is a rather inconsequential event from the perspective of individual welfare. In this sense, and despite many virtues and attractions, this class of models fails to address a central reason that job loss, unemployment, and recessions attract so much attention and concern from economists, policymakers, and others. For the same reason, care should be taken in using this class of models to form conclusions about the welfare effects of shocks and government policies.

The paper proceeds as follows. Section I presents evidence on the incidence of job destruction, layoffs, unemployment inflows, and job displacement over the business cycle. Section II first summarizes previous research on the short- and long-term consequences of job displacements for earnings. It then draws on work by von Wachter and others (2011) to estimate near-term and present-value earnings losses associated with job displacement, and to investigate how the losses vary with business cycle conditions at displacement. Section III reviews previous work on the nonmonetary costs of displacement and presents evidence on cyclical fluctuations in perceptions and anxieties related to labor market prospects. Section IV considers selected equilibrium search-and-matching models of unemployment fluctuations and evaluates their implications for the earnings and income losses associated with job loss. Section V concludes.
I. The Incidence of Job Loss and Job Displacement over Time

Figure 1 displays four time series that draw on different sources of data and pertain to different concepts of job loss. The job destruction measure captures gross employment losses summed over shrinking and closing establishments in the Business Employment Dynamics (BED) database. The layoff measure reflects data on employer-initiated separations, as reported by employers in the Job Openings and Labor Turnover Survey (JOLTS) and as aggregated and extended back to 1990 by Davis, Jason Faberman, and John Haltiwanger (forthcoming). We calculate unemployment inflow rates using monthly Current Population Survey (CPS) data on the number of employed persons and the number unemployed less than 5 weeks. Summing over months yields the quarterly rates. The measure of initial unemployment insurance (UI) claims is the quarterly sum of weekly new claims for UI benefits, expressed as a percent of nonfarm payroll employment.

Figure 1 highlights two key points. First, the sheer volume of job loss and unemployment incidence is enormous—in good economic times and bad. For example, the JOLTS-based layoff rate averages 7 percent per quarter from 1990 to 2011. Multiplying this figure by nonfarm payroll employment in 2011 yields about 9 million layoffs per quarter. Quarterly averages for job destruction and unemployment inflows are of similar magnitude. Initial UI claims average about 5 million per quarter. In short, the U.S. economy routinely accommodates huge numbers of lost jobs and unemployment spells.

Many, perhaps most, of these job loss events involve little financial loss or other hardship for individuals and families. Indeed, the high rates shown in figure 1 reflect an impressive capacity for constant renewal and productivity-enhancing reallocation of jobs, workers, and capital in the economy as a whole. It is important to keep this point in mind when interpreting

3. The BED contains longitudinally linked records for all businesses covered by state unemployment insurance agencies, making it virtually a census of nonfarm private business establishments.
4. To deal with weaknesses in the JOLTS sample design, Davis and others (forthcoming) rely on BED data to track the cross-sectional distribution of establishment-level growth rates over time. They combine micro data from the BED and the JOLTS to obtain the layoff series in figure 1. To extend the layoff series back in time before the advent of the JOLTS, they use the BED to construct synthetic, JOLTS-like layoff rates. Davis and others (2010) discuss sample design issues in the JOLTS and develop the adjustment methodology implemented by Davis and others (forthcoming).
5. See Bartlesman and Doms (2000) and Foster, Haltiwanger, and Krizan (2000) for reviews of the evidence on reallocation and productivity growth.
Sources: Bureau of Labor Statistics, Department of Labor, and Census Bureau data, Davis and others (2011), and authors’ calculations.

a. All series are seasonally adjusted quarterly rates and are scaled to the left scale except where stated otherwise. Shaded areas indicate NBER-dated recessions.

b. Rates refer to the private sector only. They are tabulated directly from establishment-level data from the Business Employment Dynamics (BED) program by Davis, Faberman and Haltiwanger (2011) for 1990Q2 to 2010Q2 and spliced to published BED statistics for 2010Q3 and 2010Q4. The splice is based on overlapping data from 2006Q1 to 2010Q2.

c. The JOLTS concept is used. Rates are constructed from JOLTS establishment-level data for 2001Q3–2010Q2 and extended back to 1990Q2 by Davis and others (2011); rates for 2010Q3–2011Q2 are constructed by summing monthly rates from JOLTS and splicing to earlier years based on overlapping data from 2006Q1 to 2010Q2.

d. Monthly rates are calculated from CPS data as the number unemployed less than 5 weeks divided by total civilian employment, then summed over months. To adjust for the 1994 CPS redesign, we divide the number of short-term unemployed by 1.1 prior to 1994. See Polivka and Miller (1998) and Shimer (2007) on the CPS redesign.

e. The sum of weekly new claims is rescaled to represent 4 1/3 weeks of claims, then divided by monthly nonfarm payroll employment from the Current Employment Statistics, then summed over months to quarterly rates. Weekly new claims data are available at www.ows.doleta.gov/unemploy/claims.asp.

b. Rates refer to the private sector only. They are tabulated directly from establishment-level data from the Business Employment Dynamics (BED) program by Davis, Faberman and Haltiwanger (2011) for 1990Q2 to 2010Q2 and spliced to published BED statistics for 2010Q3 and 2010Q4. The splice is based on overlapping data from 2006Q1 to 2010Q2.

c. The JOLTS concept is used. Rates are constructed from JOLTS establishment-level data for 2001Q3–2010Q2 and extended back to 1990Q2 by Davis and others (2011); rates for 2010Q3–2011Q2 are constructed by summing monthly rates from JOLTS and splicing to earlier years based on overlapping data from 2006Q1 to 2010Q2.

d. Monthly rates are calculated from CPS data as the number unemployed less than 5 weeks divided by total civilian employment, then summed over months. To adjust for the 1994 CPS redesign, we divide the number of short-term unemployed by 1.1 prior to 1994. See Polivka and Miller (1998) and Shimer (2007) on the CPS redesign.

e. The sum of weekly new claims is rescaled to represent 4 1/3 weeks of claims, then divided by monthly nonfarm payroll employment from the Current Employment Statistics, then summed over months to quarterly rates. Weekly new claims data are available at www.ows.doleta.gov/unemploy/claims.asp.
the evidence on the costs associated with job displacement. That evidence focuses, quite deliberately, on the types of job loss events that often involve serious consequences for workers and their families.

Second, all four series in figure 1 exhibit strongly countercyclical movements, with clear spikes in the three recessions covered by our sample period. For example, the quarterly layoff rate rises by 129 basis points from 1990Q2 to 1991Q1, 85 basis points from 2000Q2 to 2001Q4, and 208 basis points from 2007Q3 to 2009Q1. Interestingly, each measure in figure 1 starts to rise before the onset of a recession (as dated by the National Bureau of Economic Research) and turns down before the resumption of an expansion. This pattern confirms the well-known usefulness of initial UI claims as a leading indicator for business cycles, and it suggests that other job loss indicators behave similarly in this respect.

Much of our study examines the earnings losses of long-tenure male workers who lose jobs in large-scale layoff events. To quantify those losses, we follow individual workers over time using annual earnings records maintained by the Social Security Administration (SSA). Figure 2 plots an annual job displacement measure for men constructed from the SSA data and compares it with annual measures of job destruction and initial claims for unemployment insurance benefits. Here, we report displacement rates in the population of male employees 50 years or younger with at least 3 years of prior job tenure, excluding government workers and certain services industries not covered by the Social Security system throughout our full sample period. Also shown are annual series for two measures of job destruction from the Census Bureau’s Business Dynamics Statistics (BDS) program and initial claims for UI benefits.

We regard a worker as displaced in year \( y \) if he separates from his employer in \( y \) and the employer experiences a mass-layoff event in \( y \). We

6. This pattern holds in earlier postwar U.S. recessions as well. See, for example, Blanchard and Diamond (1989), Davis and Haltiwanger (1990), Davis, Faberman, and Haltiwanger (2006), and Elsby, Michaels, and Solon (2009).

8. Figure 2 cumulates weekly UI claims over 12 months, but the calculations otherwise follow the same approach as in figure 1. The BDS job destruction series are available at an annual frequency and extend further back in time than the BED-based job destruction series in figure 1, but they are not as timely. Because the BDS series reflect 12-month changes in establishment-level employment, they are not directly comparable to the BED-based job destruction series based on 3-month changes.
say a worker “separates” from an employer in year $y$ when he has earnings from the employer in $y-1$ but not in $y$. To meet the prior job tenure requirement, the worker must have positive earnings from the employer in question in $y-3$, $y-2$, and $y-1$. To qualify as a mass-layoff event in year $y$, the employer must meet the following criteria: 50 or more employees in $y-2$; employment contracts by 30 to 99 percent from $y-2$ to $y$; employment in $y-2$ is no more than 130 percent of employment in $y-3$; and

a. All series are annual rates and are scaled to the left scale except where stated otherwise. Shaded areas indicate recessions.

b. Rates of job loss in mass-layoff events among male workers 50 years or younger with at least 3 years of prior job tenure, expressed as a percent of all male employees 50 or younger with at least 3 years of tenure at firms with at least 50 employees in the same age range. See text for a definition of mass-layoff events.

c. Rates for the nonfarm private sector are from the Business Dynamics Statistics program at the U.S. Census Bureau. They are tabulated from March-to-March employment changes summed over all contracting establishments in the Longitudinal Business Database. Available at www.ces.census.gov/index.php/bds/bds_database_list

d. Annual sums of weekly new claims as a percent of total employment; series is constructed as in figure 1 except that the monthly rates are summed from April of the previous year to March of the indicated year.

e. Rates for the nonfarm private sector from the Business Dynamics Statistics calculated from establishment-level employment changes at firms with at least 50 employees.
employment in $y + 1$ is less than 90 percent of employment in $y - 2$. The 99 percent cutoff in the second condition ensures that we do not capture spurious firm deaths due to broken longitudinal links. The last two conditions exclude temporary fluctuations in firm-level employment. Although these criteria miss some displacements of long-tenure workers at larger employers, they help ensure that the separations we identify as job displacement events are indeed the result of permanent layoffs. To qualify as a job displacement event in $y$, we also require that the separation be from the worker’s main job, defined as the one that accounts for the largest share of his earnings in $y - 2$. For additional details on the data, sample, and measurement procedures, see von Wachter and others (2011).

To express job displacements in year $y$ as a rate in figure 2, we divide by the number of male workers 50 or younger in $y - 2$ with at least 3 years of job tenure at firms with 50 or more employees in the industries covered by Social Security throughout our sample period. These workers make up 31 to 36 percent of all male workers 50 or younger in industries continuously covered by the SSA from 1980 to 2008, depending on year, 40 to 48 percent when we also restrict attention to those with 3 or more years of job tenure, and 70 to 74 percent when we further narrow the focus to firms with 50 or more employees.

The annual frequency of the measures in figure 2 somewhat obscures the timing of cyclical movements, but the broad patterns echo those in figure 1: job loss rates move in a countercyclical manner, and recessions involve notable jumps in job loss. The deep recession in the early 1980s saw dramatic increases in rates of job destruction and job displacement. For example, the annual job destruction rate at firms with 50 or more employees rose from 11.6 percent in 1979 to 18.3 percent in 1983. (To be clear, the latter figure reflects establishment-level employment contractions that occur from March 1982 to March 1983.) Our measure of the job displacement rate rose from 1.9 percent in 1980 to 5.0 percent in 1983. More generally,
the job displacement rate is roughly 20 to 25 percent as large as annual job destruction rates, although it is worth stressing that the two measures pertain to different at-risk populations.

The incidence of job displacement might seem modest in any given year, but it cumulates to a large number during severe downturns. For example, summing the job displacement rates in figure 2 from 1980 to 1985 yields a cumulative displacement rate of more than 20 percent. This figure translates to about 2.7 million job displacement events over the 6-year period among men 50 years or younger with 3 or more years of job tenure and working in industries with continuous SSA coverage. This figure is conservative, given our restrictive criteria for mass-layoff events. According to the Displaced Worker Supplement to the CPS, 6.9 million persons with at least 3 years of prior tenure lost jobs due to layoffs from 2007 to 2009 (Bureau of Labor Statistics 2011). This figure includes women and does not impose our mass-layoff criteria. The Bureau of Labor Statistics also reports that an additional 8.5 million persons were displaced in 2007–09 from jobs held less than 3 years.

The top panel of figure 3 shows displacement rates for men with 3 to 5 years of job tenure and for men with 6 or more years. We impose the same requirements for age, firm size, industry coverage, and mass-layoff events as before. Displacement rates are considerably higher for workers with 3 to 5 years of tenure and more cyclically sensitive in the relatively shallow recessions and weak labor markets of the early 1990s and 2000s. These patterns conform to the view that workers with lower job tenure face greater exposure to negative firm-specific and aggregate shocks. The bottom panel shows displacement rates for men in three broad age groups. The basic pattern is clear: younger men tend to be more exposed to negative firm-specific and aggregate shocks that lead to job destruction.

Together, the two panels of figure 3 show that longer job tenure and greater labor market experience afford some insulation from the vicissitudes of firm-level employment fluctuations. However, it is well worth noting that tenure and experience provide less insulation in the deep aggregate downturn in the early 1980s. This aspect of figure 3 suggests that severe

11. In calculating the data for this figure, we allow the at-risk population to change from year to year. For some purposes it is more appropriate to consider the cumulative displacement rate for a fixed at-risk population. Consider, for example, the population of male workers younger than 50 with 3 or more years of job tenure at firms with at least 50 employees as of 1979, and working in industries with continuous SSA coverage. By our criteria 16 percent of this fixed population experienced a job displacement event during 1980–85.

a. All series are annual rates. Both panels refer to men 50 or younger with at least 3 years of job tenure who lose jobs in mass-layoff events. See text and figure 2 for full definitions and methods.
recessions bite especially deeply into the distribution of valuable employment relationships. Evidence below on the cyclical behavior of the earnings losses associated with job loss supports this view as well.

II. The Long-Term Earnings Effects of Job Displacement

We turn now to evidence on the earnings losses associated with job displacement.

II.A. Previous Research

A growing body of research finds that job displacements often lead to large, persistent earnings losses. Most studies estimate the effect as the change in earnings from before to after the job loss relative to the contemporaneous earnings change of comparable workers who did not lose jobs. Studies differ somewhat in how they measure job loss and how they define the control group of nondisplaced workers.

Following earlier research, von Wachter and others (2011) define job displacement as the separation of a “stable” worker from his main employer during a period when the employer experiences a lasting employment decline of at least 30 percent. A stable worker is one with positive earnings at the firm in each of the three years immediately prior to the displacement event. Their definition also requires the employer to have at least 50 employees in the baseline period before the mass layoff. They exclude workers in two-digit industries not covered by SSA in the early 1980s, chiefly the public sector. Comparing the evolution of annual earnings for displaced workers with that of a control group of similar workers who did not separate in the displacement year or the next 2 years, von Wachter and others (2011) find that displacements in the early 1980s led to average annual earnings losses relative to the control group of more than 30 percent of predisplacement annual earnings. Despite some recovery over time, even after 20 years the earnings of displaced workers remain 15 to 20 percent below the level implied by control group earnings.

The short- to medium-run effects of job displacement are larger in depressed areas and sectors. For example, using information on earnings and employers from UI records and a comparable definition of job displacement, Louis Jacobson, Robert Lalonde, and Daniel Sullivan (1993) find that job displacement in Pennsylvania in the early 1980s led on average to near-term earnings losses of more than 50 percent. Five years after displacement, the losses average 30 percent of predisplacement earnings,
and they do not substantially fade even 10 years later (von Wachter and Sullivan 2009). Robert Schoeni and Michael Dardia (2003) and Yolanda Kodrzycki (2007) find similar results for job displacement in manufacturing industries in the mild recession of the early 1990s in California and Massachusetts, respectively.

Earnings losses are large and long lasting even in regions and periods with stronger labor markets. For example, Kenneth Couch and Dana Placzek (2010) examine job displacement using quarterly earnings data from UI records in Connecticut in the 1990s. They find that long-tenured workers suffer losses in earnings up to 5 years after a job displacement. Similarly, Jacobson and others (1993) show that workers displaced in Pennsylvania counties with below-average unemployment rates and above-average employment growth fare significantly better than the average displaced worker, but still suffer earnings losses. Von Wachter and others (2011) find substantial earnings losses for job displacements during the late-1980s expansion, losses that fade only after 15 years. Other studies (for example, Topel 1990, Ruhm 1991, and Stevens 1997) use longitudinal survey data to compare earnings of job losers with those of a control group. These studies typically do not focus on depressed areas or periods, but they also find large and persistent losses in earnings and wages.

The findings from administrative data pertain to annual or quarterly earnings. Hence, the earnings losses potentially arise from reductions in both employment and wages. However, the earnings loss for the median worker in the sample is about as large as, and more persistent than, the mean loss (von Wachter and others 2011, Schoeni and Dardia 2003). This result and survey-based evidence that most job losers return to employment (for example, Farber 1999) suggest that the bulk of earnings losses after job displacement reflect reductions in wage rates or hours worked.

One natural question about studies based on administrative data is how the earnings loss results depend on the definition of job displacement, the choice of control groups, and the specification of mass-layoff events. Von Wachter and others (2011) find that their results survive the use of alternative firm size thresholds, different definitions of mass layoffs, alternative employment stability requirements for control groups, and other robustness checks. Von Wachter, Elizabeth Handwerker, and Andrew Hildreth (2008) obtain similar results using control groups constructed from workers in similar firms and industries. Studies based on panel survey data that do not impose restrictions on firm size or firm events yield results for earnings similar to results based on administrative data (for example, Topel 1990, Ruhm 1991, Stevens 1997).
Overall, a central finding in previous research is that job displacement leads to large and long-lasting earnings losses, especially under weak labor market conditions. This observation suggests that workers who have experienced job displacement events since 2008 are likely to suffer unusually severe and persistent earnings losses. Direct evidence on the losses of recently displaced workers is limited, however, in part because of lags in processing and analyzing administrative data sources. The latest Displaced Worker Supplement (DWS) to the CPS, conducted in January 2010, contains recall data for workers displaced during 2007–09. Given the absence of a control group, the inability to incorporate earnings losses due to employment reductions, and the presence of measurement error in wages and job loss events, the DWS data tend to show smaller earnings losses than studies based on administrative data (von Wachter and others 2008). However, even the DWS data imply substantial earnings losses for persons who lost jobs during 2007–09. On the basis of the DWS data, the Bureau of Labor Statistics (2011) reports that only 49 percent of workers with 3 or more years of job tenure who were displaced during 2007–09 were employed as of January 2010, and that among the reemployed, 36 percent reported current earnings at least 20 percent lower than on the previous job.

The earnings losses associated with job displacement are large and persistent for both women and men and in all major industries. Older workers tend to have larger immediate losses than younger workers. Relative to a control group of nondisplaced workers of similar age, however, the losses of younger displaced workers are nonnegligible and persist over 20 years (von Wachter and others 2011). Earnings losses tend to rise with tenure on the job, industry, or occupation (for example, Kletzer 1989, Neal 1995, Poletaev and Robinson 2008). Yet losses for workers with 3 to 5 years of job tenure are substantial and long lasting, and even workers with less than 3 years of job tenure experience nonnegligible declines in annual earnings following a job displacement event (von Wachter and others 2011).

II.B. Estimated Earnings Losses Associated with Job Displacement

We now follow von Wachter and others (2011) in estimating the earnings effects of job displacement and their sensitivity to economic conditions at the time of displacement. We define job displacement as in section I: the separation of long-tenure men, 50 years or younger, in mass-layoff events at firms with at least 50 employees at baseline. We also provide some results for women and for older men. To estimate the effects of job displacement, we compare the earnings path of workers who experience
job displacement with the earnings path of similar workers who did not separate during the same time period, while controlling for individual fixed effects and differential earnings trends.

We implement this comparison by estimating the following distributed-lag model separately for each displacement year $y$ from 1980 onward:

$$ e_{it}^y = \alpha_i^y + \gamma_i^y \lambda_i^y + \beta_i^y X_{it} + \sum_{k=1}^{20} \delta_i^y D^1_{it} + \mu^y, $$

where the outcome variable $e_{it}^y$ is real annual earnings of individual $i$ in year $t$ in 2000 dollars (deflated using the consumer price index), $\alpha_i^y$ are coefficients on worker fixed effects, $\gamma_i^y$ are coefficients on calendar-year fixed effects, $X_{it}$ is a quartic polynomial in the age of worker $i$ at year $t$, and the error $\mu^y$ represents random factors. To allow further differences in annual earnings increments by a worker’s initial level of earnings, the specification includes differential year effects that vary proportionally to the worker’s predisplacement average earnings, $-e_{it}^y$, calculated using the years $y-5$ to $y-1$. The $D^k_{it}$ are dummy variables equal to 1 in the worker’s $k$th year before or after his displacement, and zero otherwise, where $k=1$ denotes the displacement year and $k=0$ denotes the final year of earnings with the predisplacement employer. In the 1985 displacement-year regression, for example, $D^5_{it}=1$ for $t=1989$ and zero otherwise for a worker $i$ who experiences displacement in 1985 by our criteria.

We estimate equation 1 by displacement year using annual, individual-level observations in the SSA data from 1974 to 2008. To construct our regression sample for displacement year $y$, we start with a 1 percent sample of men with a valid Social Security number in $y$. We then keep those that had positive Social Security earnings in $y$ and impose the same restrictions with respect to firm size, industry, worker age, and job tenure as in figure 2. We then select data on workers displaced in $y$, $y+1$, and $y+2$ plus data on workers in a control group described below. We include displacements that occur in $y+1$ and $y+2$ in the sample for displacement year $y$ to raise the number of observations of displaced workers, and to align the inclusion windows for displaced and control group workers. Note that this approach smooths the estimated earnings effects of job displacement from one displacement year to the next, which works against finding differences between recessions and expansions.
The earnings data for the control group help identify the year effects $\gamma_i$ and $\lambda_i$. Given the presence of the year effects and worker fixed effects in equation 1, the coefficients $\delta_{ik}$ on the dummies $D_{ik}$ measure the time path of earnings changes for job separators from 6 years before and up to 20 years after a displacement, relative to the baseline and relative to the change in earnings of the control group. The baseline consists of years 7 and 8 before displacement. To interpret the estimated $\delta_{ik}$ coefficients as the earnings effect of job displacement requires that, conditional on worker fixed effects and the other control variables, the control group earnings capture the counterfactual earnings of displaced workers in the absence of job displacement. Mechanically, to obtain the counterfactual earnings path of a displaced worker $i$ absent displacement, we evaluate equation 1 at $D_{ik} = 0$ for all $k$.

For the displacement-year $y$ regression sample, the control group consists of workers not separating in $y$, $y + 1$, and $y + 2$ (“nonseparators”). Hence, as is typical in the literature on job displacement based on administrative data, we exclude so-called non-mass-layoff separators from $y$ to $y + 2$ from the control group. Non-mass-layoff separators are workers who quit their jobs or were laid off by firms with an employment drop of less than 30 percent. We impose the same restrictions with respect to firm size, industry, worker age, job tenure, and sex, as for displaced workers. We discuss the impact of alternative control groups and concerns related to potential selection bias in the earnings loss estimates in section II.D.

Figure 4 reports results for men 50 or younger with at least 3 years of job tenure as of the displacement year. The top panel shows the average time paths of mean raw earnings before and after displacement for workers displaced in recessions and expansions. If a peak or trough falls within a given calendar year, we weight the year according to the number of its months in expansion or recession when computing the averages. The middle panel shows the average earnings loss profiles for workers displaced in recessions and in expansions, relative to the control group, and normalized to reflect changes relative to mean earnings in years $t - 4$ to $t - 1$ before displacement. To obtain average earnings losses for job displacements

---

13. Since our sample window stops in 2008, for displacement years after 1988 we do not observe 20 years of earnings data after a displacement. For these years, the postdisplacement dummies are included up to the maximum possible number of years.

14. For 1980 the baseline is years 5 and 6 before displacement, and for 1981 it is years 6 and 7 before displacement. We also drop the dummy variable for the first calendar year in each regression. These zero restrictions, two for the baseline and one for the first calendar year, resolve the potential collinearity among the dummy variables in equation 1.
in expansions and recessions, we average over estimated values of $\delta_k$ in recession and expansion years, respectively. The bottom panel shows these losses as a fraction of predisplacement mean earnings.

The bottom panel of figure 4 shows that the earnings losses of displaced workers relative to the control group are very large initially: 39 percent of predisplacement earnings in the first year for displacements that occur in recessions and 25 percent for displacements that occur in expansions. They are also long lasting, ranging from 15 to 20 percent from 10 to 20 years out for displacements that occur in recessions and about 10 percent for those that occur in expansions. These estimates are robust to many alternative specifications, as discussed below and in von Wachter and others (2011). For example, the earnings losses are similar if one defines a mass-layoff event as a firm-level employment decline of at least 80 percent rather than...
30 percent. They are slightly larger for workers with 6 years or more of job tenure, the main comparison group of Jacobson and others (1993), and slightly smaller for workers with 3 to 5 years of job tenure.

Figure 5 plots estimated short-term earnings losses against the national unemployment rate in the year of displacement. We define the short-term earnings loss as the loss in year $t + 2$ for a job displacement in $t$, as estimated from equation 1, divided by predisplacement mean earnings in years $t - 4$ to $t - 1$. The figure displays a clear inverse relationship. Regressing the earnings loss on the unemployment rate at displacement yields an $R^2$ of 0.22 and a slope coefficient of $-0.022$ (with a standard error of 0.008). That is, a rise in the unemployment rate from 5 percent to 9 percent at the time of displacement implies that the earnings loss in the third year of displacement increases from 18 percent to 26 percent of average annual earnings.

Source: Authors’ calculations.

a. In each panel the curve labeled “In recessions” shows average outcomes for workers displaced in recession years from 1980 to 2005, and the curve labeled “In expansions” shows average outcomes for those displaced in expansion years in that period. When a given displacement year straddles recession and expansion periods, that year’s values are apportioned according to the number of months in each period (see the text for further details). Displaced workers are men 50 or younger who separate from their main job in a mass-layoff event and who have at least 3 years of prior job tenure. All averages are estimated using administrative data on W-2 earnings (following von Wachter and others 2011) and include observations with zero earnings.

b. Mean annual raw earnings before and after displacement of workers displaced in recessions and of those displaced in expansions.

c. Average earnings losses of displaced workers, as estimated from displacement-year regression models of annual earnings for displaced workers and control group workers. The regression models include controls for worker effects, a quartic polynomial in age, calendar-year effects, and an interaction of the latter with individual average earnings in the 5 years preceding displacement. See equation 1 and the accompanying discussion for further details.

d. Earnings losses in the middle panel expressed as a percent of displaced workers’ average annual earnings in the predisplacement baseline period.

Figure 4. Earnings of Displaced Male Workers before and after Displacement (Continued)
predisplacement earnings. Since the earnings recovery pattern in the bottom panel of figure 5 is approximately parallel in expansions and recessions, figure 6 suggests that the state of the labor market at displacement sets the initial level of losses, from which a gradual recovery ensues. We will use this result when calculating present-value earnings losses in the next subsection.

**II.C. Present-Value Earnings Losses Associated with Job Displacement**

Figures 4 and 5 point to large short-term and long-term earnings losses associated with job displacement and large earnings loss differences between displacements that occur in expansions and those that occur in recessions. To estimate the present discounted value (PDV) of the annual
earnings losses summarized in figure 4, we proceed as follows. Using a real interest rate of 5 percent, we sum the discounted losses over a 20-year period starting with the year of displacement. Since we do not observe the full 20 years of earnings after a job displacement for workers displaced in later years, we impose a common rate of decay past the 10th year. Hence, the estimated mean PDV earnings losses for displacements that occur in, say, a recession are

\[
P_{\text{Loss}}^R = \sum_{i=1}^{10} \tilde{\delta}_i^R \frac{1}{(1 + r)^i} + \sum_{i=11}^{20} \tilde{\delta}_i^R \frac{(1 - \lambda)^{i-10}}{(1 + r)^{i-1}},
\]

where \( \tilde{\delta}_s \) is the average estimated earnings loss in year \( s \) after displacement (derived by averaging equation 1 estimates over displacement-year regression).
sions), and \( \overline{\delta}_t^{10}(1-\overline{\lambda})^{t-10} \) is an extrapolated earnings loss using the common decay rate \( \overline{\lambda}. \) The evolution of earnings losses is roughly parallel for displacements in expansions and recessions, so we use the average decay rate of earnings losses from years 11 to 20 after displacement, estimated using data for all available workers and years.\(^{15}\)

Other approaches are possible. Rather than a common decay rate, we could use estimated earnings losses for the largest available sample of years and workers for each value of \( s \) up to \( s = 20. \) That approach, however, involves a different mix of years for each value of \( s \), and for large values of \( s \) the sample would be dominated by displacement events in the 1980s. Moreover, as the sample of workers displaced in a given year ages and their labor force participation declines, the estimates for long after the displacement year may be affected by changes in composition and greater sampling error in the increasingly smaller samples. Similarly, using actual estimates for the long-run follow-up period may put weight on cohorts that experience particularly long-lasting effects. Given our aim to approximate the average PDV loss for a typical worker in boom years and in recession years, we choose a common decay rate for all displacement cohorts. To smooth out sampling variability in the recovery pattern and to maximize the number of available cohorts, we calculate the decay rate as the average of annualized log differences in earnings losses from years 6 to 10 to years 11 to 15 after displacement. This approach balances the influence of displacements in the early 1990s, which reflect a strong recovery in the high-pressure labor market of the mid- to late 1990s, with the influence of displacements in other periods.

Since earnings levels change over time and may differ between displacements that occur in expansions and those that occur in recessions, we consider two ways of normalizing the absolute earnings losses. First, we scale the PDV earnings loss by displaced workers’ mean annual earnings in years \( t - 4 \) through \( t - 1 \) before displacement. This approach expresses the loss as the number of earnings years lost at the previous level of earnings. Second, we express the PDV earnings loss as a percentage of PDV earnings along a counterfactual earnings path in the absence of displacement. To do so, we first construct the counterfactual by adding the absolute value of the estimated earnings loss (middle panel of figure 4) back to the actual level of average earnings (top panel of figure 4). In the notation of equation 1, for workers displaced in year \( y \), we thereby effectively obtain

\[ \text{1ST PAGES} \]
Using the mean earnings of displaced workers as a benchmark ensures that we average over the right worker fixed effects and obtain the right earnings levels. We then take the average of the counterfactual in years belonging to recessions and the average in years belonging to expansions. Using these averages, we divide the PDV earnings loss by the resulting PDV of counterfactual earnings in booms and recession, respectively.

Table 1 reports these alternative measures of the PDV earnings loss after a job displacement, again for men 50 years or younger with at least 3 years of positive earnings at an employer with at least 50 workers. The definition of displacement is the same as in figure 4. The first row shows estimated PDV earnings losses, averaged over all displacement years, of $77,557. This amounts to 1.71 years of average predisplacement earnings and 11.9

Source: Authors’ calculations using equation 2 and estimates from equation 1.

a. PDVs are calculated over 20 years of job displacement at an annual discount rate of 5 percent. Mass-layoff events are defined as in section I. See text for further description.

b. When a year contains both expansion and recession months or monthly unemployment rates that fall in different ranges, that year’s values are allocated proportionally to the number of months in each cyclical state or range.

c. Counterfactual earnings are what the displaced worker would have earned over the same 20 years had he not been displaced.

\[ \bar{e}_{t} = \bar{\alpha} + \gamma_{t} + \beta_{t} \bar{X}_{t} \]. Using the mean earnings of displaced workers as a benchmark ensures that we average over the right worker fixed effects and obtain the right earnings levels. We then take the average of the counterfactual in years belonging to recessions and the average in years belonging to expansions. Using these averages, we divide the PDV earnings loss by the resulting PDV of counterfactual earnings in booms and recession, respectively.

Table 1 reports these alternative measures of the PDV earnings loss after a job displacement, again for men 50 years or younger with at least 3 years of positive earnings at an employer with at least 50 workers. The definition of displacement is the same as in figure 4. The first row shows estimated PDV earnings losses, averaged over all displacement years, of $77,557. This amounts to 1.71 years of average predisplacement earnings and 11.9

16. Similarly, we calculate the corresponding mean of actual annual earnings before and after displacement by first obtaining the average for each displacement year, \( \bar{e}_{j}^{\text{act.}} \), and then averaging over the years belonging to expansions and recessions.
percent of the PDV of counterfactual earnings. The next two rows show our
measures of PDV earnings losses separately for expansions and recessions.
As anticipated from figure 4, job displacements lead to very large declines
in PDV earnings, and the losses are much larger for displacements occur-
ing in recessions. The average worker displaced in a recession experiences
PDV losses of $109,567, equivalent to 2.50 years of average predisplace-
ment earnings, and an 18.6 percent loss relative to counterfactual earnings.
In contrast, the PDV earnings loss experienced by workers displaced in an
expansion averages $72,487, which amounts to 1.59 years of predisplace-
ment earnings and an 11.0 percent shortfall relative to the counterfactual.

Recall from figure 1 that the incidence of job displacement is also much
greater in recessions. Given that displacements have more severe conse-
quences in recessions, the unweighted averages over years in the first row
of table 1 effectively give less weight to persons displaced in recessions,
and thus understate average PDV earnings losses taken over all displaced
workers. Similarly, because we weight all recession years equally, and
recessions with higher displacement rates also involve higher earnings
losses, table 1 understates the average PDV earnings losses for job dis-
placements that occur in recessions.

The last five rows of table 1 show how estimated PDV earnings
losses vary with the unemployment rate in the year of displacement. The
unemployment rate reflects contemporaneous labor market conditions in a
different way than business cycle dating. As before, to calculate the table
entries, we first estimate PDV earnings losses by year of displacement. We
then average over all years falling into an indicated unemployment range,
assigning fractional weights to years that fall partly into a given range. The
results show that PDV earnings losses rise steeply with the unemployment
rate in the year of job displacement. This important finding strongly rein-
forces and extends the evidence in figure 5.

To take this result one step further, we repeat our procedure for cal-
culating PDV earnings losses by year of displacement. We now depart
from working with averages over multiple displacement years and con-
sider a separate earnings loss path for each displacement year. When we
have more than 10 years of postdisplacement information, we use the first
10 years and extrapolate from year 11 to year 20 using the same average rate
of decay as before. When we have less than 10 years of postdisplacement
information (that is, starting in 1999), we also use the available information
for other years to construct decay rates in the earlier postdisplacement
years. For displacement years with less than 10 but more than 5 years of
postdisplacement data, we set the decay rate to the annualized log differ-
ence of losses between the 6th and the 10th year after displacement, taken from displacement years for which this information is available. For those years with less than 6 displacement years, we use the annualized log differences of losses between the 2nd and the 5th displacement year. For years closer to the end of our sample period, we necessarily rely more heavily on extrapolation.

Figure 6 plots the resulting PDV earnings losses (expressed as multiples of average annual predisplacement earnings) against the unemployment rate in the year of displacement. The figure again shows an approximately linear relationship, which is not surprising given the roughly linear relationship in figure 5 and our use of a common decay rate beyond the 10th year after displacement. Even allowing for different postdisplacement recovery patterns, the figure suggests that PDV earnings losses increase approximately linearly with the unemployment rate in the year of displacement. A linear regression of the PDV loss measure on the unemployment rate at displacement yields an $R^2$ of 0.27 with a slope coefficient of $-0.23$ (standard error of 0.08). Thus, an increase in the unemployment rate at displacement from 5 percent to 9 percent implies that PDV earnings losses rise from 1.6 years to 2.5 years of predisplacement earnings. When we add an indicator for recession years to this descriptive regression model, it is not statistically significant.

Table 2 shows PDV earnings losses for displaced women and for various age and tenure subgroups of displaced men. The PDV earnings losses due to job displacement are large for all these groups. They are smaller for women than for men, but not dramatically so in the last two columns, which effectively control for differences in average earnings levels between men and women. For example, the average losses for women amount to 1.5 years of predisplacement earnings (table 2), compared with 1.7 years for the corresponding group of men (table 1). Comparison of tables 1 and 2 also shows that the losses are larger for men with longer job tenure before displacement. The panels reporting results for male age subgroups show that, except for men displaced near the end of their working lives, PDV earnings losses are much larger for displacements that occur in recessions.

II.D. On Selection Bias and Sensitivity to Control Group Choice

We now discuss two potential concerns about the earnings loss estimates that underlie our results in figures 4 to 6 and tables 1 and 2, namely,

a. PDVs are calculated over the 20 years following displacement as described in table 1, except as noted below.
b. Ages and years of tenure are as of time of displacement. Values for years containing both expansion and recession months or monthly unemployment rates that fall in different ranges are calculated as described in table 1.
c. Counterfactual earnings are what the displaced worker would have earned over the same 20 years had he or she not been displaced.
d. PDVs are calculated over 15 years.
e. PDVs are calculated over 10 years.
selection bias and the sensitivity of our results to the choice of control group. Relative to nonseparators (our control group), non-mass-layoff separators experience earnings losses that are smaller and less persistent than the losses experienced by mass-layoff separators. Thus, if we include non-mass-layoff separators in the control group, the estimated earnings losses due to job displacement become smaller. Von Wachter and others (2011) estimate a version of equation 1 with non-mass-layoff separators as part of the control group. This change in the composition of the control group reduces the estimated earnings losses by about one-quarter. Von Wachter and others also consider instrumental variables estimates that are not affected by the presence of voluntary separators, which we discuss below, and obtain results very similar to those reported here. After considering various estimators, they confirm the conclusion from previous research that the “true” loss at displacement is closer to the estimates that exclude non-mass-layoff separators from the control group.

Estimates based on equation 1 may overstate earnings losses at displacement because displaced workers are negatively selected on observable and unobservable characteristics with respect to the control group: employers may lay off workers who are less productive and have less future earning potential. Von Wachter and others (2011) conduct an in-depth investigation of this question and conclude that earnings losses based on equation 1 are robust to a range of important sensitivity checks. The presence of worker fixed effects in equation 1 implies that selection based on fixed worker attributes with a time-invariant effect on earnings poses no problem. However, different trends in counterfactual earnings between displaced workers and the control group may introduce a bias. For example, it is well known that different parts of the earnings distribution experience different earnings growth rates (see, for example, Autor and Katz 1999). Since displaced workers have lower average earnings before displacement than nondisplaced workers, our regression models include interactions between average earnings in the 5 years before displacement and fixed effects for calendar years. Von Wachter and others also present estimates that include differential trends by two-digit industry and by other observable characteristics of workers and firms before displacement. The estimates are reasonably robust to these modifications and decline only somewhat with the inclusion of industry-specific trends.

However, ex ante differences in unobservable characteristics between treatment and control groups can still lead to different counterfactual earn-
ings trends. In this context, von Wachter and others (2011) address two types of selection: that within and that between employers. To address the concern that displaced workers are negatively selected on potential unobserved earnings trends within firms, they replicate equation 1 using the mass-layoff event at the firm level as an instrumental variable for displacement. That is, they use a dummy for the year of the mass layoff at the firm, \( D_{fit} \), where \( f(i) \) is the worker’s employer, to instrument for the dummy of the individual layoff (\( D_{it} \)). Hence, the comparison is now between the earnings of all workers at firms undergoing mass layoffs and the earnings of all workers at non-mass-layoff firms. Using this type of firm-level indicator to instrument for displacement, and controlling for differential trends by pre-mass-layoff characteristics at the firm level, von Wachter and others obtain results very similar to those reported here based on equation 1. This instrumental variables estimator is also robust to the presence of non-mass-layoff separators, since the instrument should be orthogonal to the rate of retirement or voluntary mobility.

To address the potential concern that workers with lower potential earnings trends sort into firms more likely to experience mass layoffs, von Wachter and others (2011) follow previous work and consider a version of equation 1 that includes firm fixed effects. This specification yields somewhat smaller estimated earnings losses, because the losses of workers remaining at firms with mass layoffs are now subtracted from the losses of the displaced workers. It is not clear whether the decline in earnings for those remaining at mass-layoff firms should be subtracted or treated as part of the outcome. In any event, the estimated losses for the displaced workers remain substantial and very persistent. Von Wachter and others conclude that estimates based on equation 1, on which we rely, are robust to a range of important sensitivity checks. Hence, despite some variation depending on the exact specification, we believe our calculations based on estimated versions of equation 1 provide a reasonable characterization of the magnitude and persistence of the individual earnings losses caused by job displacement.

III. Other Costs of Job Displacement and Unemployment

Section II focused on earnings losses associated with displacement events. We turn now to the effects of job displacement on other outcomes such as consumption, health, mortality, and children’s educational achievement. We also present new evidence on cyclical movements in worker anxieties.
and perceptions about the risk of job loss and the ease or difficulty of job finding.

III.A. Effects on Income, Consumption, and Employment Stability

It is not easy to estimate the effects of job displacement on consumption and income. Few, if any, data sets that track large numbers of workers over time contain high-quality information about consumption outcomes. Likewise, very few data sets that track large numbers of workers include the data on earnings, asset incomes, and public and private transfer payments needed to identify income responses to job displacement events. Moreover, transfer payments are understated greatly in many household surveys that include such information (Meyer, Mok, and Sullivan 2010).

The few studies that estimate the effects of job loss or unemployment on consumption typically find sizable near-term declines in consumption expenditure but lack evidence on long-term consumption responses. See Gruber (1997) and Stephens (2004), for example. The consumption responses tend to be concentrated at the lower end of the income distribution (Browning and Crossley 2001, Congressional Budget Office 2004). Although transfer programs often mitigate the earnings loss due to job displacement, the replacement amounts are quite modest compared with our estimates of present-value earnings losses. Even the generous, long-lasting benefits available under the German unemployment insurance system replace only a modest share of the earnings loss associated with job displacement (Schmieder, von Wachter, and Bender, 2009).

Previous research also finds that job displacement leads to other adverse consequences. Lasting postdisplacement earnings shortfalls occur alongside lower job stability, greater earnings instability, recurring spells of joblessness, and multiple switches of industry or occupation (Stevens 1997, von Wachter and others 2011). Much of the increased mobility between jobs, between industries, and between occupations probably reflects privately and socially beneficial adjustments. On average, however, displaced workers who immediately find a stable job in their predisplacement industry obtain significantly higher earnings. Lower job stability and higher earnings volatility persist up to 10 years after displacement. Thus, there is no indication that laid-off workers trade a lower earnings level for a more stable path of employment and earnings.

III.B. Effects on Health, Mortality, Emotional Well-Being, and Family

There is also evidence that displaced workers suffer short- and long-term declines in health. Survey-based research in epidemiology finds that
layoffs and unemployment spells involve a higher incidence of stress-related health problems such as strokes and heart attacks (see, for example, Burgard, Brand, and House 2007).

Whereas studies of self-reported health and job loss outcomes face significant challenges related to measurement error and recall and selection bias, the analysis of mortality outcomes can exploit large administrative data sources that are less subject to these problems. Sullivan and von Wachter (2010) study the effects of job displacement on mortality outcomes over the 20 years following displacement, using administrative data on earnings and employers from the Pennsylvania UI system and mortality data from the SSA. Their results show that mature men who lost stable jobs in Pennsylvania during the early 1980s experienced near-term increases in mortality rates of up to 100 percent. The initial impact on mortality falls over time, but it remains significantly higher for job losers than for comparable workers throughout the 20-year postdisplacement period. If sustained until the end of life, the higher mortality rates for displaced workers imply a reduction in life expectancy of 1 to 1.5 years.

Because the 1980s recession was especially deep in Pennsylvania and involved unusually large earnings losses for displaced workers, the mortality effects estimated by Sullivan and von Wachter (2010) reflect a very bad case scenario. It is reasonable to expect smaller mortality effects of job displacements in most other years and places. Unfortunately, labor market conditions nationwide in the past 3 years have also been dismal, with persistently high unemployment rates. Thus, the mortality estimates in Sullivan and von Wachter may well provide a suitable guide to mortality effects for recently displaced American workers. The available evidence indicates that job displacement also raises mortality rates in countries with universal public health insurance systems and generous social welfare systems, such as Sweden (Eliason and Storrie 2009) and Norway (Rege, Telle, and Votruba 2009). These studies find higher mortality rates in the years following job displacement, but they contain little information about long-term effects.

Several studies point to short- and long-term effects of layoffs on the children and families of job losers and unemployed workers. In the short run, parental job loss reduces the schooling achievement of children (Stevens and Schaller 2009). In the long run, it appears that a lasting reduction in the earnings of fathers reduces the earnings prospects of their sons (Oreopoulos, Page, and Stevens 2008). Patrick Wightman (2009) also finds that parental job loss is harmful for the educational attainment and cognitive development of children. Other studies find that layoffs raise the incidence
of divorce, reduce fertility, reduce home ownership, and increase the rate of application to and entry into disability insurance programs (Charles and Stephens 2004, von Wachter and Handwerker 2009, Rupp and Stapleton 1995). Last but not least, and perhaps not surprisingly given the magnitude and range of adverse consequences discussed above, job loss and unemployment also lead to a reduction in happiness and life satisfaction (see Frey and Stutzer 2002).

Clearly, care should be taken in drawing welfare conclusions and policy prescriptions from the range of adverse consequences associated with job displacement. However, this brief review makes clear that job displacement entails a variety of significant short- and long-run costs for affected workers and their families. Neither the large present-value earnings losses we estimate nor the estimated consumption responses capture the full measure of costs associated with job displacement.

III.C. Cyclical Movements in Worker Anxieties and Perceptions

Given the severity of job displacement effects on earnings and other outcome measures, it is natural to ask how worker anxieties and perceptions about labor market conditions track actual conditions. Evidence on this issue is potentially informative in several respects. First, if recessions or high unemployment rates cause employed workers to become more fearful about layoffs and wage cuts, they involve psychological costs beyond the direct effects on job-losing workers and their families. Second, perceptions about labor market conditions are likely to influence search behavior by employed and unemployed workers, including those who experience a displacement event. Third, high worker anxiety about labor market conditions is likely to undermine consumer confidence and depress consumption expenditure. Fourth, perceptions about labor market conditions have important influences on policymaking, politics, and electoral outcomes. Because they potentially influence so many voters, anxieties about labor market conditions may have more important political consequences than actual conditions.

A long-running source of data on perceptions about labor market conditions is the General Social Survey (GSS), a repeated cross-sectional

18. Stevens (2004) provides survey-based evidence that subjective assessments of job loss probabilities have considerable predictive power for future layoffs at the individual level, even when conditioning on standard demographic variables that are correlated with layoff risks. Nevertheless, his main empirical specification yields no evidence of a relationship between job loss expectations and household consumption conditional upon losing a job.
household survey conducted since 1972. The GSS includes two categorical response questions that are useful for gauging cyclical movements in perceptions about labor market conditions. One question asks the respondent about the perceived likelihood that he or she will lose a job or be laid off in the next 12 months. The other asks about the perceived difficulty of finding a job with the same income and fringe benefits as the respondent’s current job.

The top panel of figure 7 shows, for each available year in the GSS, the percentage of prime-age workers who consider it “very likely” or “fairly likely” that they will lose a job or be laid off in the next 12 months. The figure plots these values against the average CPS unemployment rate in the 5-month window that brackets the corresponding GSS interview months. There is a strong, positive relationship: an increase in the prime-age unemployment rate from 4 percent to 8 percent raises from 10 percent to 15 percent the share of prime-age workers who perceive job loss as fairly or very likely. The online appendix shows a very similar pattern for all employed workers 18 to 64 years of age.

The bottom panel of figure 7 shows the percent of prime-age workers who perceive it to be “not easy” to find a job with income and fringe benefits similar to those in their current job. Plotting these values against contemporaneous unemployment rates, we again find a strong relationship: an increase in the prime-age unemployment rate from 4 percent to 8 percent raises from 35 percent to 52 percent the share of prime-age workers who regard it as hard to find another job with a comparable compensation package. In this context it is also worth noting that quit rates are highly procyclical (see, for example, Davis and others 2011). Quit rates plummeted in the most recent recession and remain extraordinarily low, another indication that workers perceive good jobs as hard to find.

Gallup polls provide another long-running, consistent source of data on perceived labor market conditions. The Gallup data cover a shorter time period than the GSS data, but they pertain to a highly eventful period in terms of economic developments. In addition, one of the Gallup measures is available at a (roughly) monthly frequency, which is useful for assessing the shorter-term relationship between perceived and actual conditions. Figure 8 draws on the Gallup data to plot over time the percent of adult interviewees who respond yes to the following question: “Thinking about the job situation in America today, would you say that it is now a good time or a bad time to find a quality job?” The responses are highly cyclically sensitive. As the labor market tightened, the share of yes responses rose from about 20 percent in early 2003 to nearly 50 percent in the first
Figure 7. Perceived Likelihoods of Job Loss and Job Finding versus the Contemporaneous Unemployment Rate, Prime-Age Workers, 1977–2010

1. Each point corresponds to a GSS survey year and plots the share of prime-age respondents in that year giving the indicated response against the average of seasonally adjusted monthly unemployment rates in January through May of the same year. (GSS interviews take place in February, March, and April.) Prime-age workers are employed adults aged 25 to 54, excluding active-duty armed forces, persons who report self-employment as their main job, and institutionalized persons. Oversamples of blacks in the GSS in certain years are excluded. Responses are weighted using the WTTSALL variable.

2. The full question is “Thinking about the next 12 months, how likely do you think it is that you will lose your job or be laid off—very likely, fairly likely, not too likely, or not at all likely?” (GSS variable JOBLOSE).

3. The full question is “About how easy would it be for you to find a job with another employer with approximately the same income and fringe benefits you now have? Would you say very easy, somewhat easy, or not easy at all?” (GSS variable JOBFIND).

Source: Authors’ calculations using tabulations of micro data from the GSS and unemployment data from the CPS.
half of 2007. It then dropped to about 10 percent over the next 2 years and has remained at very low levels ever since. This evidence suggests that perceptions about labor market conditions respond rapidly to actual conditions.

Table 3 reports data from Gallup polls conducted during the month of August in 1997 and every year from 2003 to 2011. The table shows a tremendous increase in worker anxiety levels following the peak of the financial crisis in the latter part of 2008 and early 2009. The percentages of employed adults expressing worries that they personally would experience a cutback in hours, a wage cut, a benefit cut, or a layoff in the near future jumped dramatically. After some lessening between August 2009 and August 2010, the most recent data for August 2011 show worker anxiety returning to peak or near-peak levels.

In summary, the evidence presented in figures 7 and 8 and table 3 indicates that worker perceptions about labor market conditions are closely attuned to actual conditions. The Gallup polling data, in particular, point to a dramatic deterioration in perceptions about labor market conditions and prospects after the financial crisis—a deterioration that persists to the
present day and that involves widespread concerns about layoff risks, wage and benefit cuts, shorter hours, and the difficulty of finding a good job. Whether or not these fears show up in realized earnings outcomes, they involve psychological costs in the form of heightened anxiety for much of the population.

IV. The Effects of Job Loss in Leading Theoretical Models of Unemployment and Labor Market Dynamics

Mortensen and Pissarides (1994) present an equilibrium search-and-matching model that, in various formulations, has become the leading framework for analyzing aggregate unemployment fluctuations. We now evaluate how well certain versions of the Mortensen-Pissarides (MP) model account for our evidence on the magnitude and cyclicality of the earnings losses associated with job displacement.  

19. There appear to be few previous efforts to evaluate whether equilibrium search-and-matching models can account for the earnings losses associated with job displacement. An exception is Den Haan, Ramey, and Watson (2000). Davis (2005) provides some back-of-the-envelope calculations. The loss of earnings potential upon job loss is an important element in the theoretical model of high European unemployment rates developed by Ljungqvist and Sargent (1998).

a. Based on polling of workers employed full or part time. The survey question is “Next, please indicate whether you are worried or not worried about each of the following happening to you, personally, in the near future. How about [the following are rotated] that your hours at work will be cut back? that your wages will be reduced? that your benefits will be reduced? that you will be laid off?”
IV.A. MP Models of Unemployment Fluctuations

Shimer (2005) considers a basic version of the MP model with risk-neutral workers and firms, uniform match quality, Nash bargaining, and a constant rate of job destruction and job loss. Aggregate shocks drive employer decisions about vacancy posting and fluctuations in job creation, job finding, and unemployment. Shimer shows that the basic MP model delivers too little volatility in unemployment for reasonable specifications of the aggregate shock process (see also Costain and Reiter 2008). Under Nash bargaining, the equilibrium wage largely absorbs shocks to labor productivity in the basic model. As a result, realistic shocks have little impact on employer incentives to post vacancies, and the model generates small equilibrium responses in job finding rates, hiring, and unemployment. This unemployment volatility puzzle has motivated a great deal of research in recent years.

One prominent strand of this research stresses the consequences of wage rigidities.20 Hall and Milgrom (2008), for example, step away from Nash bargaining while retaining privately efficient compensation and separation outcomes. They replace Nash bargaining with the alternating-offer bargaining protocol proposed by Ken Binmore, Ariel Rubinstein, and Asher Wolinsky (1986). Whereas the standard Nash wage bargain treats termination of the match opportunity as the threat point, the threat point in Hall and Milgrom’s “credible bargaining” setup is a short delay followed, with high probability, by a resumption of bargaining. This change in bargaining regime goes a long way to insulate the equilibrium wage bargain from aggregate shocks and outside labor market conditions.

A key point is that the cost of a small delay during the bargaining process is less cyclical than the value of outside opportunities. Hence, closing the basic MP model in the manner of Hall and Milgrom leads to greater sensitivity of the employer surplus value to aggregate shocks and bigger responses in vacancies, job finding rates, and unemployment. Hall and Milgrom show that their specification of the bargaining environment resolves the unemployment volatility puzzle in a reasonably calibrated version of the basic MP model.

In our analysis below, we adopt Hall and Milgrom’s credible bargaining version of the basic MP model and two versions with Nash bargaining. We follow this approach for two reasons. First, Hall and Milgrom offer perhaps the most successful version of the basic MP model in terms of explaining

the cyclical behavior of job finding rates, vacancies, and unemployment. Second, by comparing the credible bargaining and Nash versions of the model, we can determine whether a particular form of wage rigidity improves the model’s ability to account for the facts about earnings losses associated with job loss.

Despite much attention to the basic MP model in recent work, the model misses some first-order features of labor market fluctuations. The basic MP model cannot reproduce the recessionary spikes in job destruction, job loss, and unemployment inflows depicted in figures 1 and 2. Moreover, the model has no role for hires and separations apart from job flows. There is no search by employed workers, no job-to-job movement, and no replacement hiring. As a related point, the basic model entails no heterogeneity of productivity, match surplus values, or wages. This sort of heterogeneity seems important for generating large earnings losses due to job loss. Given these limitations, we also consider a model of Burgess and Turon (2010) that extends Mortensen and Pissarides (1994) by incorporating search on the job and other changes. Burgess and Turon’s model produces hires and separations apart from job flows and recessionary spikes in job destruction, job loss, and unemployment inflows.

There are also good reasons to anticipate that the model of Burgess and Turon will generate larger earnings losses associated with job loss than the basic MP model. Like models by Kenneth Burdett and Mortensen (1998) and by Fabien Postel-Vinay and Jean-Marc Robin (2002) and other models that include search on the job, their model generates persistent heterogeneity in match surplus values and wages for workers of a given quality. It also delivers a job “ladder” whereby newly reemployed workers tend to obtain jobs on the lower rungs of the wage distribution initially and to move up the wage distribution over time through search on the job. This job ladder feature prolongs the period of earnings recovery after displacement. Finally, Andreas Hornstein, Per Krusell, and Giovanni Violante (2010) show that plausibly parametrized versions of basic search models yield very modest levels of frictional wage dispersion, which implies little scope for earnings losses due to job loss when unemployment spells are short. Hornstein and others also consider several extensions to basic search models, and among those they consider, the only ones that offer much scope for cross-sectional wage dispersion are models with search on the job.

**IV.B. Income and Earnings Losses in the Basic MP Model**

Source: Authors’ calculations.

\(^a\) All present-value calculations use a 5 percent annual discount rate. All model calibrations follow Hall and Milgrom (2008) in their choice of parameter values and the transition matrix of a five-state Markov process for aggregate shocks. See the online appendix for a more detailed description of the simulations and calculations.

\(^b\) Calibration is similar to that in Shimer (2005) and Hall (2005).

\(^c\) Model entails sequential bargaining with disagreement costs à la Binmore, Rubinstein and Wolinsky (1986). Calibration is that of Hall and Milgrom (2008).

\(^d\) We compute the present value income losses in the top row directly from value functions. For each aggregate state, we calculate the difference between the asset value of employment and the asset value of unemployment and express the difference relative to the asset value of employment. Performing this calculation for the five aggregate states yields the reported ranges.

\(^e\) Each indicated model is simulated for 1,000 draws of the aggregate path, with each draw starting from the middle aggregate state and evolving according to the aggregate transition matrix. Each draw is simulated for 5,000 working days (20 years at 250 working days per year). The realized paths are tracked for 5,000 day-1 job losers and 1,000 day-1 employed persons on each of the 1,000 aggregate paths.

\(^f\) Calculated as \(\bar{\Omega}^{25} \sum_{i=1}^{25} (1 - \bar{\Omega})^{i-1}\), where \(\bar{\Omega}\) is the daily job finding rate, assuming 25 job seeking days per month.

\(^g\) For the income calculations, an individual receives the imputed income value of leisure if unemployed on a given day, and the annuity value of the wage bargain if employed. At the end of the simulation horizon, each individual is assigned the asset value associated with that individual’s state on day 5,000. This results in a realized income path plus terminal value for each individual, which is then used to compute the realized PDV of income for an unemployed worker as of day 1. This quantity is then compared with that of the mean realized present value income of the day-1 employed persons on the same aggregate path.

\(^h\) For the earnings calculations, each individual is assigned zero earnings if unemployed and the annuity value of the wage bargain if employed. To focus on PDV earnings over a 20-year horizon comparable to the empirical estimates in section II, the terminal value is set to zero at the end of the 5,000-day simulation horizon. The PDVs of the realized earnings paths for individuals who become unemployed on day 1 are then compared with the mean realized present value earnings for 1,000 individuals who remain employed on day 1 on the same aggregate path. Because earnings loss statistics are very similar across all three variants of the MP model, results are reported only for the credible bargaining version of the basic MP model.

\(^i\) The 1,000 aggregate paths are ranked by realized mean PDV income or earnings loss. This panel reports statistics for the paths ranked from 90 to 110 (the 20 paths nearest the 10th percentile) by this metric.

\(^j\) Statistics are reported for the paths ranked from 890 to 910 (the 20 paths nearest the 90th percentile) by mean PDV income or earnings loss.
with Nash bargaining—a standard calibration similar to that of Shimer (2005) and another calibration similar to that of Marcus Hagedorn and Iourii Manovskii (2008). These two calibrations differ chiefly in the level of income imputed to the unemployed, which we interpret as the sum of UI benefits, the value of additional leisure and home production activity, and any savings on work-related costs. Hagedorn and Manovskii set this value to a level nearly as large as the productivity of the employed, thereby amplifying the equilibrium response of unemployment to aggregate shocks. The standard calibration involves a much larger gap between productivity and the imputed income value of unemployment, yielding much smaller equilibrium responses to shocks of a given size. Our calibrations follow Hall and Milgrom (2008) in their choice of parameter values for each version of the basic MP model. See the online appendix for a detailed discussion of the model simulations and our calculations for the present-value losses associated with job loss.

The first row of table 4 highlights an important message: job loss and unemployment are a rather inconsequential event for persons living in the basic MP world. With a 5 percent annual discount rate, job loss reduces the present value of income by about 0.2 percent in the MP-CB and standard MP-Nash versions of the model and by less than 0.05 percent in the Hagedorn-Manovskii calibration. We compute these present-value income losses directly from value functions. That is, for each of five aggregate states we calculate the difference between the asset value of employment and the asset value of unemployment, expressing the difference relative to the former. Performing this calculation for all five aggregate states yields the reported ranges. If these results capture the real-world costs of job loss, one might well wonder why all the fuss—why are job loss and unemployment perceived as important economic phenomena and potent political issues?

The rest of the table reports statistics on unemployment, job finding, and the distribution of present-value income and earnings losses for the different models. To compute these statistics, we simulate aggregate and individual paths. Starting in the middle aggregate state, we simulate 1,000 aggregate paths for each version of the model, letting each simulation run for 20 years (5,000 days at 250 working days per year). Along each aggregate path, we simulate paths for large numbers of workers who either lose jobs or remain employed on day 1. Flow income equals the annuity value of the wage bargain when employed and the imputed flow value of unemployment otherwise. The PDV of income includes the discounted asset value of the individual’s realized terminal state. To compute the realized income loss for a day-1 job loser, we compare the PDV of that individual’s
realized income path with the mean realized PDV of income for persons who remain employed on day 1 on the same aggregate path. In this way, by comparing day-1 job losers with persons who remain employed along the same aggregate path, we obtain a comparison between the treatment group (day-1 job losers) and the controls (day-1 employed).

To compute the realized earnings loss for a day-1 job loser, we compare the PDV of that individual’s realized earnings path over the 20-year horizon with the mean PDV of realized earnings for individuals living on the same aggregate path who remain employed on day 1. Earnings equal the wage when employed and zero when unemployed. We set the terminal value to zero to match the 20-year horizon in our empirical estimates of PDV earnings losses. Thus, the earnings losses in table 4 are larger than the corresponding income losses for two reasons: earnings exclude the imputed income value of unemployment, and we set terminal values to zero in the earnings comparisons.

Consider the results for the MP-CB model in the first panel of simulations in table 4. Averaging over all day-1 job losers on all aggregate paths yields an average realized PDV income loss of 0.23 percent. This figure essentially replicates the income loss result for the MP-CB model in the top row, as it should. However, the simulation approach enables us to compute the full distribution of outcomes: the 90th-percentile income loss in the MP-CB version is only 1.04 percent, still a rather modest value, and job losers at the 10th percentile of the distribution actually experience a gain of 0.51 percent in PDV income.

Turning to earnings losses, we report results for the MP-CB version only, because the other two versions yield very similar results. Mean PDV earnings losses are 1.28 percent in the basic MP model—an order of magnitude smaller than the 11.9 percent figure in the last column and first row of table 1. One potential concern about this earnings loss comparison is that table 1 considers losses associated with job displacement events, which by design exclude many job loss events that involve little or no loss of earnings or income. So there is a sense in which we have compared average job loss outcomes in the basic MP model with bad-case outcomes in the data. Although this argument has some force, we do not find it persuasive. The estimated earnings losses reported in section II pertain to an ex ante identifiable group of workers (men 50 or younger with 3 or more years of job tenure at firms with 50 or more employees), and this group accounts for a large share of U.S. employment. We would like a theoretical model that explains the magnitude and cyclicality of the PDV earnings losses associated with job loss for this large group.
The remaining panels in table 4 consider selected aggregate paths defined by the mean realized PDV income or earnings losses. “Boom” paths are those near the 10th percentile of average losses for day-1 job losers, and “bust” paths are those near the 90th percentile. Mean PDV income losses remain small along both boom and bust paths. Even when we isolate the worst 1 percent of individual outcomes along the bust paths, the PDV income losses amount to only 2.2 percent in the CB and standard Nash versions of the model and only 0.7 percent in the Hagedorn-Manovskii calibration. In short, the basic MP model cannot produce large welfare losses for job losers, even at the extremes of aggregate and individual outcomes. The model can produce large PDV earnings losses at the extremes of the distribution of individual outcomes. For example, the worst 1 percent of individual outcomes yield earnings losses comparable to the mean loss reported in table 1. This result, however, hardly amounts to a success for the model.

Why are the consequences of job loss so modest in the basic MP model? Two aspects of the model deliver the result almost immediately. First, wages are uniform in the cross section, so that unemployment spells are the only source of earnings loss upon job loss. Second, when calibrated to job finding rates typical of the postwar U.S. experience, expected unemployment durations are short, about 2 or 3 months. Short unemployment spells coupled with uniform wages in the cross section imply small earnings losses associated with job loss.

The basic MP model also implies a close relationship between the cost of job loss to the worker and the vacancy supply condition (as has been stressed to us by Robert Hall). Given free entry, the zero-profit condition for job-creating employers says that the daily vacancy filling rate times the asset value of a filled job equals the daily flow cost of maintaining a vacancy. The JOLTS data imply a vacancy filling rate of about 5 percent per day. Drawing on work by Jose Silva and Manuel Toledo (2009) and Hagedorn and Manovskii (2008), Hall and Milgrom (2008) conclude that the daily flow cost of a vacancy is about one-half of a worker’s daily output. Thus, the employer’s asset value of a newly filled job is equivalent to about 10 days of the output generated by a (newly hired) worker. If employer and worker share equally in the surplus generated by a new match, then the worker’s value of transitioning from unemployment to employment is

21. We could refine the treatment-control comparisons in table 4 by replicating the employment stability criterion used for controls in section II. This type of refinement may make sense in future research. Given the uniformity of wages and the small consequences of job loss in table 4, however, we do not think the basic MP model can explain the evidence on earnings losses or rationalize strong concerns about job loss and unemployment.
also about 10 days of output. In other words, not much value is at stake in the creation and destruction of employment relationships in the basic MP model. Richer models in the MP class need not imply such a tight relationship between the cost of filling a new job and the surplus value of the average existing job.

In summary, we draw three conclusions from table 4 and the related discussion. First, job loss is a rather inconsequential event for individual welfare in the basic MP model, even at the extremes of individual and aggregate outcomes. Second, the basic MP model cannot rationalize the empirical evidence on PDV earnings losses associated with job displacement. Third, although wage rigidity of the form considered by Hall and Milgrom (2008) greatly improves the ability of the basic MP model to explain aggregate unemployment fluctuations, it does not bring the model closer to the evidence on the magnitude and cyclicality of earnings losses associated with job displacement.

**IV.C. Losses in an MP Model with Job Destruction Spikes and Search on the Job**

Burgess and Turon (2010) depart from Mortensen and Pissarides (1994) by introducing search on the job, at a cost, and by adopting a different vacancy creation process that gives meaning to the concept of a job apart from an employer-worker match. Specifically, they assume a finite supply elasticity of potential new job creation each period, so that firms find it optimal to refill certain jobs left open by departing workers. Like Mortensen and Pissarides (1994), their model also differs from the basic MP model in capturing cross-sectional heterogeneity in match products and surplus values. These extensions lead to cross-sectional wage dispersion, a distinction between job flows and worker flows, and endogenous job destruction spikes in the wake of negative aggregate shocks. The model also gives rise to a job ladder that prolongs the recovery of predisplacement earnings for job-losing workers.

The model is set in continuous time. Idiosyncratic productivity shocks arrive according to independent Poisson processes, and aggregate productivity, \( p \), follows a three-state Markov chain. When hit by an idiosyncratic shock, a job draws a new idiosyncratic productivity value in the interval \([-\sigma, \sigma]\), possibly higher or lower than the previous value. Optimizing behavior yields three idiosyncratic productivity thresholds, as shown in figure 9. If idiosyncratic productivity exceeds \( S(p) \) in a filled job, the worker’s net expected gains to search are negative. For productivity less than \( S(p) \) in a filled job, the worker’s net expected gains to search are positive. If the
worker finds a vacant job, he quits and the firm decides whether to search for a replacement. It does so if idiosyncratic productivity exceeds $T(p)$; otherwise, it lets the job lapse. If a filled job draws a new idiosyncratic productivity value below $R(p)$, the job is destroyed and the worker experiences job loss. As the figure indicates, the productivity thresholds are functions of the aggregate state. A negative shock to $p$ shifts $R(p)$ to the right, triggering a burst of job destruction. An important implication is that job losses due to idiosyncratic shocks occur throughout the distribution of productivities, whereas job losses due to aggregate shocks occur only for low-value jobs.

Table 5 reports PDV income and earnings losses for the model of Burgess and Turon. We modify their calibration to generate job finding rates and unemployment spell durations comparable to postwar U.S. experience. The top panel reports results for a period of time corresponding to 3 months with no change in the aggregate state. The remaining two panels involve transitions between states and focus on outcomes for workers who lose jobs in the early part of a downturn, roughly corresponding to the recessionary spikes in job destruction and job loss seen in figures 1 and 2. All loss calculations pertain to workers who separate from their employer in job destruction events and exclude separations that result from search on the job.

The first two rows of table 5 report PDV income and earnings losses for job losers in the good, middle, and bad aggregate states. We compute the income losses using differences in value functions at each level of idiosyncratic productivity, $\varepsilon$, and then integrate over the distribution of $\varepsilon$ that prevails in the indicated aggregate state to obtain the mean PDV income losses. These losses are larger than in the basic MP model, but they remain quite modest: about 0.3 to 0.4 percent.

For earnings losses we adopt a simulation approach similar to the one used for table 5. However, we now compare the realized PDV earnings of

---

22. See the online appendix for a version of table 5 that adopts their calibration, which is meant to match features of the British economy from 1964 to 1999.

Source: Authors’ calculations.

\(a\). Burgess and Turon’s (2010) search-and-matching model differs from the basic MP model in capturing search on the job, a distinction between job flows and worker flows, heterogeneity in wages and match surplus values, and spikes in aggregate job destruction. It also adopts a different vacancy creation process that gives content to the concept of a job apart from the employer-worker match. Job destruction and job loss arise from negative aggregate shocks and sufficiently bad idiosyncratic shocks. We depart from Burgess and Turon’s calibration (which was designed to match features of the U.K. economy) by increasing the arrival rate of idiosyncratic shocks (from 0.15 to 0.25) and the efficiency of the matching function (from 0.6 to 1.1). These changes yield more rapid flows through the unemployment pool and higher monthly job finding rates, roughly in line with U.S. outcomes. The unemployment rate is 5.2 percent in the middle state in our calibration. See the text for further description of the model and the online appendix for a detailed explanation of the loss calculations and the underlying simulations.

\(b\). Results are for a period of time corresponding to 3 months with no change in the aggregate state.

\(c\). Calculated from value function comparisons.

\(d\). Calculations rely on simulations of aggregate and individual paths over 20-year horizons (80 quarters), where earnings are set to the wage if the individual is employed and to zero if not. The wage when employed depends on the aggregate state and the idiosyncratic productivity level of the job.

\(e\). “Own past” comparisons calculate losses relative to the job loser’s pre-displacement employment value evaluated at the old aggregate state and expressed relative to the same employment value. The value of unemployment is calculated at the new aggregate state.

\(f\). Inflow-weighted averages of PDV losses associated with idiosyncratic and aggregate shocks. The weights are given by the share of job loss due to idiosyncratic shocks during the quarter and the share triggered by a negative aggregate shock.

\(g\). “Control group” comparisons calculate losses relative to the job loser’s pre-displacement employment value evaluated at the new aggregate state. The value of unemployment is also calculated at the new aggregate state.

\(h\). Calculations that result in zero loss do so because all workers in the lower tail of the productivity distribution lose their jobs when hit by a negative aggregate productivity shock, and all get the value of unemployment in the new state.

workers who lose jobs characterized by a given \(\varepsilon\) with the mean realized PDV earnings among workers who remain employed (in the displacement period) at the same value of \(\varepsilon\). Once we obtain the comparison for each \(\varepsilon\), we integrate with respect to the appropriate distribution to obtain the mean realized PDV earnings loss. As before, we use a 20-year horizon for the earnings calculations. The online appendix describes the model simulations and PDV calculations in detail.

The remaining panels consider job loss events that occur in the quarter when the economy gets hit by a negative aggregate shock. Job loss events now arise for two reasons. As before, a flow of negative idiosyncratic
shocks produces a stream of job loss events. In addition, the negative aggregate shock erases the surplus value of marginal jobs, producing a burst of job destruction and job loss. All workers at jobs below the new, higher destruction threshold $R$ become unemployed in the wake of a negative aggregate shock. That is, for treatment-control comparisons conditional on the idiosyncratic productivity value $\varepsilon$, all workers below the new destruction threshold are in the same position. (Hence, losses are zero in the row in each panel that reports the “mean loss due to aggregate shock.”) For control group comparisons, job loss produces PDV income losses of about 0.3 percent in these “recession” periods (last row of the middle panel). The disproportionate loss of marginal jobs in the wake of a negative aggregate shock pulls down the average present-value income loss. So the model of Burgess and Turon does not shed much light on why job loss events in recessions are more consequential.

With respect to earnings, our calibrated version of the Burgess and Turon model produces nontrivial PDV losses. For a given aggregate state, the losses reported in the top panel of table 5 range from 2.4 to 2.7 percent of PDV earnings, about one-quarter of the empirical PDV earnings losses reported in tables 1 and 2. Thus, search on the job and heterogeneity in match surplus values clearly help move the model closer to the evidence on the PDV earnings losses associated with job loss.

In this respect, the job ladder feature of the model plays an important role. The online appendix displays the cross-sectional wage function, the density of all filled jobs, and the density of first jobs for newly reemployed workers who leave unemployment. For our calibrated version of the model, the maximum wage in the good aggregate state exceeds the minimum wage by 49 percent. The density of first jobs is much more concentrated at the low end of the wage distribution than the density of all jobs. The average difference between the predisplacement wage and the wage on the first postdisplacement job is 10 percent in the good aggregate state, 8.4 percent in the middle state, and 6.7 percent in the bad state. These observations and statistics are different ways of saying that the model incorporates a significant job ladder.

A few additional remarks are in order. First, in generating the results in table 5, we do not impose a job tenure requirement on either displaced

23. In practice, empirical treatment-control comparisons do not perfectly condition on the idiosyncratic component of jobs and match values. However, as long as the empirical specification at least partly captures a disproportionate loss of marginal jobs in the wake of a negative aggregate shock, the composition effect we highlight here will also be present in the empirical estimates of earnings losses associated with job loss in a recession.
workers or control group workers. Doing so may increase the earnings losses. Second, search intensity is a binary decision variable in the model of Burgess and Turon. Variable search intensity for employed workers, as in work by Matthias Hertweck (2010), may generate an elongated climb up the job ladder after displacement and, as a result, produce larger PDV earnings losses. We conclude that job ladder models can produce nontrivial earnings losses due to job displacement but are unlikely to account for the bulk of observed losses. For one thing, they do not explain why the earnings of displaced workers remain well below that of control group workers 10 or more years after displacement. Moreover, it does not appear that a pure job ladder model can rationalize the striking cyclical pattern in PDV earnings losses that we documented in section II.

V. Concluding Remarks

Long-tenure workers who lose jobs in mass-layoff events experience large and persistent earnings losses compared with otherwise similar workers who retain their jobs. That is the central message of a now-sizeable literature on the earnings losses associated with job displacement. We focus on displacements from 1980 to 2005 among men 50 or younger with 3 or more years of prior job tenure. For this group, job loss in a mass-layoff event reduces the present value of earnings by an estimated $77,557 (in 2000 dollars) over 20 years at a 5 percent annual discount rate, equivalent to 1.7 years of predisplacement earnings. Losses are larger for men with greater job tenure. They are smaller for women, even as a multiple of predisplacement earnings.

Present-value losses rise steeply with the unemployment rate at the time of displacement. The average loss equals 1.4 years of predisplacement earnings if unemployment at displacement is less than 6 percent, and 2.8 years if unemployment exceeds 8 percent. More generally, the evidence in tables 1 and 2 and figures 4 to 6 says that tight labor market conditions at displacement strongly improve the medium- and long-term future

24. Postel-Vinay and Robin (2002) consider a different model with search on the job and heterogeneity in productivity on both sides of the labor market. Employers have all the bargaining power, and newly reemployed workers start at the bottom of the wage distribution after an unemployment spell. When an employed worker finds an attractive outside opportunity, the incumbent employer may respond with a successful counteroffer (a wage increase). Thus, the model of Postel-Vinay and Robin also yields a prolonged earnings recovery path after job loss that is tied to search on the job, but wage gains may or may not coincide with job changes.
earnings prospects of displaced workers. The highly procyclical behavior of job finding rates among the unemployed implies that tight labor market conditions strengthen near-term reemployment and earnings prospects as well. Seen in this light, economic policies that set the stage for strong growth and low unemployment are highly beneficial to displaced workers. Indeed, pro-growth policies may be the most efficient and cost-effective means available to policymakers to alleviate the hardships experienced by displaced workers.

Previous work shows that job displacement also has negative consequences for employment and earnings stability, household consumption expenditure, health and mortality outcomes, children’s educational achievement, and subjective well-being. We present evidence that worker perceptions about layoff risks, job finding prospects, and the likelihood of wage cuts closely track cyclical fluctuations in actual labor market conditions. Perception measures point to a tremendous increase in worker anxieties about labor market prospects after the financial crisis of 2008, an increase that persists through August 2011. It seems likely that these high anxiety levels produce important stresses and psychological costs for a large segment of the population.

We also consider whether models of unemployment fluctuations along the lines of the canonical contribution by Mortensen and Pissarides (1994) can account for the earnings losses associated with job displacement. Basic versions of the MP model featured in much recent research imply theoretical earnings losses an order of magnitude smaller than empirical losses. The explanation is straightforward. The basic model has uniform wages in the cross section and, when calibrated to U.S. job finding rates, short unemployment spells. Thus, job loss has little impact on present-value earnings. Because so little is at stake in the destruction of employment relationships in the basic MP model, it cannot rationalize the earnings losses associated with job displacement.

Lastly, we evaluate an MP model of Burgess and Turon (2010) with search on the job and replacement hiring. Unlike the basic MP model, Burgess and Turon’s model is at least qualitatively consistent with several first-order features of the data: cross-sectional wage dispersion, worker flows in excess of job flows, and recessionary spikes in job destruction and unemployment inflows. The model also exhibits a job ladder that prolongs the earnings recovery path after displacement. When calibrated to match U.S. job finding rates, job loss in the model produces present-value earnings losses that, on average, are about one-quarter of the mean empirical losses due to job displacement. This is a sizable improvement over the
basic MP model, but it leaves a very large gap between theory and evidence. Moreover, the model cannot explain the larger losses for displacements that occur in recessions, because negative aggregate shocks trigger the destruction of lower-value jobs.

In our view, a major shortcoming of existing MP models of unemployment fluctuations is their implication that job loss is a rather inconsequential event for the affected workers. The consequences of job displacement, and fears of displacement, are among the main reasons that recessions and high unemployment create so much concern in the general population. The negative consequences of job displacement are why unemployment is such a potent political issue. We also think the serious consequences of job displacement are a major reason that unemployment and unemployment fluctuations attract so much attention from economists.

It is important to put our criticism of MP models in proper context. We see MP models, in particular, and the larger class of Diamond-Mortensen-Pissarides models as a great advance. These models deliver a coherent theory of frictional unemployment and its determinants. They provide an analytical framework for studying cyclical movements in unemployment, vacancies, job finding rates, and the joint dynamics of worker flows and job flows. They provide tools for analyzing search-and-matching behavior by employers and job seekers, and for studying the implications of search-and-matching frictions for wage dispersion and individual wage dynamics. These tools are widely used to study the effects of policies, wage setting arrangements, and other economic institutions on unemployment and a variety of other labor market outcomes.

We hope to see these models taken in directions that can explain large and lasting earnings losses at job displacement. There are potentially several ways to bring MP-type models closer to the evidence on the earnings losses associated with job displacement. Models that incorporate learning about match quality over time (as in Jovanovic 1979), the acquisition of specific skills through learning-by-doing on the job, and investments in specific training (as in Becker 1962) could yield substantial earnings losses upon job loss. These three mechanisms influence match durability and the evolution of surplus values in ongoing matches. It would be useful to integrate these mechanisms into MP models of unemployment fluctuations, which have thus far devoted much greater attention to the forces governing match formation. Robert Topel (1990) and Derek Neal (1995), among others, argue that specific forms of human capital play a central role in determining the magnitude of earnings losses associated with job displacement. Lars Ljungqvist and Thomas Sargent (1998) build an equilibrium
search model that hardwires a link between job loss and the destruction of human capital, and that includes further human capital depreciation during unemployment.

Workers may also enjoy rents for reasons apart from search-and-matching frictions and returns on specific human capital. Other explanations for worker rents include fairness norms and concerns about pay equity (Akerlof and Yellen 1982), high pay as a device to deter shirking (Bulow and Summers 1986), the appropriation of quasi-rents generated by sunk investments (Grout 1986, Caballero and Hammour 2005), and worker sharing of product market rents. Paul Beaudry and John DiNardo (1992) stress the role of long-term contracting and one-sided commitment as a source of downward wage stickiness. Johannes Schmieder and von Wachter (2010) consider workers who receive higher wages as a consequence of tight labor market conditions in the past. They find evidence that these workers experience higher layoff rates and lose their wage premiums upon job loss, a pattern of results that supports the presence of rents. Whether this pattern accounts for larger earnings losses in recessions, when displacements are more widespread, is an open question.

Workers who enter the labor market in periods of slack conditions suffer negative effects on future earnings that persist for 10 years or more (see, for example, Kahn 2010). Both lasting declines in employer quality and lasting effects of low starting wages on wage growth within firms contribute to the persistent negative earnings effects of slack conditions at entry (see, for example, Oreopoulos, von Wachter, and Heisz 2010). These results are interesting, in part, because new entrants have not accumulated job-specific rents and are unlikely to have accumulated much in the way of specific human capital. Apparently, weak conditions at the time of labor market entry slow the accumulation of rents and specific human capital for many years thereafter. Similar forces could lower the future earnings prospects of workers who are displaced in recessions and slumps.

B. Model Simulations and Calculations

1. Model of Hall and Milgrom (Table 4)

Following Hall and Milgrom (2008), define the asset value of unemployment as

\[ U_i = z + \frac{1}{1 + r} \sum_i \pi_{i,i'} \left[ \phi(\theta_i)(W_{i'} + V_{i'}) + (1 - \phi(\theta_i))U_{i'} \right], \]

where:

- \( z \) is the income value of leisure and other nonmarket activity, inclusive of unemployment benefits
- \( r \) is the daily rate of interest
- \( \phi(\theta_i) \) is the daily job-finding probability for unemployed workers in aggregate state \( i \), a function of the vacancy-unemployment ratio \( \theta \)
- \( \pi_{i,i'} \) is the daily probability of transitioning from state \( i \) to state \( i' \), and
- \( W_i \) is the worker’s value of the wage bargain in state \( i \).

The asset value of employment, net of the value of the wage bargain, is given by

\[ V_i = \frac{1}{1 + r} \sum_i \pi_{i,i'} \left[ (1 - s)V_{i'} + sU_{i'} \right], \]

where \( s \) is the daily rate at which workers separate from jobs.

Let \( w_i \) be the annuity value of the wage bargain for an employed worker in aggregate state \( i \). This annuity value solves the system of equations,

\[ W_i = w_i + \frac{1 - s}{1 + r} \sum_i \pi_{i,i'} W_{i'}, \text{ for } i = 1, \ldots, 5. \]

In matrix notation, we can write the vector of annuity values as
\[ w = \left[ I - \left( \frac{1-s}{1+r} \right) \Pi \right] W. \]

For Panel A in Table 4, we work directly with value functions and calculate the percentage loss in present value income due to job loss in aggregate state \( i \) as

\[ \text{Inc}_i \text{Loss} = 100 \left[ \frac{W_i + V_i - U_i}{W_i + V_i} \right]. \]

Each entry in Panel A reports the range of these loss values across the 5 aggregate states for the indicated model and calibration.

The remaining panels rely on simulated aggregate and individual-level outcomes for each model. Panel A tells us that mean present value income losses differ very little across aggregate states for a given model and calibration. Partly for this reason, and partly for the sake of brevity, we start all simulations in the middle aggregate state.

The simulations for the income loss calculations proceed as follows:

1. Set the initial aggregate state to \( i=3 \), the middle state.

2. Draw 1,000 aggregate daily paths using the transition matrix \( \Pi \). Let each aggregate path proceed for 5,000 days, which corresponds to 20 years at 250 days per year. The evolution of the aggregate state along a given aggregate path determines the evolution of the daily job-finding probability \( \phi(\theta_i) \).

3. On each aggregate path, track realized income flows for 5,000 persons who become unemployed on day 1. After day 1, persons transition between unemployment and employment according to the probabilities \( \phi(\theta_i) \) and \( s \). An individual’s realized income flows are given by
\[ Flow_{t,i} = \begin{cases} w_{t,i}, & \text{if employed at } t \text{ in state } i; \\ z, & \text{if unemployed.} \end{cases} \]

4. At the terminal date \( T=5,000 \), assign each individual the asset value of his employment status, either \( W_i + V_i \) if employed or \( U_i \) if unemployed.

5. Compute the day-1 present value of the realized income path for persons who lose jobs on day 1 as

\[
\tilde{U} (\text{Income, Day } 1) = z + \sum_{t=1}^{T} \left( \frac{1}{1+r} \right)^{t-1} flow_{t,i} + \left( \frac{1}{1+r} \right)^{T} A_{i,T},
\]

where \( A_{i,T} \) is the terminal asset value of the individual’s employment status.

6. The foregoing simulations produce 5,000 values of \( \tilde{U} (\text{Income, Day } 1) \) for each aggregate path. The corresponding realized present value income losses due to job loss, expressed as a percentage of the asset value of employment, are given by

\[
R_{\text{Inc. Loss}} = 100 \left[ \frac{W + V - \tilde{U} (\text{Income, Day } 1)}{W + V} \right],
\]

where the asset values are evaluated at the initial aggregate state \( i=3 \).

The realized income loss calculations in Table 4 report summary statistics on the individual-level values of \( R_{\text{Inc. Loss}} \) for all aggregate paths (Panel B) and subsets of aggregate paths (Panels C to D). These panels also report mean values taken over aggregate paths for the unemployment rate and the monthly job-finding rate.

The simulations for the earnings loss calculations proceed as follows: Steps 1 and 2 are the same as above. Step 3 is also the same, except that \( z=0 \). In Step 4, we set the terminal asset value to 0 to focus on 20-year earnings horizons. We modify Step 5 to obtain
\[ \bar{U}(\text{Earnings, Day 1}) = 0 + \sum_{t=1}^{T} \left( \frac{1}{1+r} \right)^{t-1} \text{flow}_{i,t}(z = 0), \]

where \( \text{flow}_{i,t}(z = 0) \) is the realized path of earnings for the individual in question.

Along each aggregate path, we also simulate the earnings paths for 1,000 persons who remain employed on day 1. Following the same approach as for day-1 job losers, we calculate the present value of their earnings over a 20-year horizon,

\[ \bar{E}(\text{Earnings, Day 1}) = w_i + \sum_{t=1}^{T} \left( \frac{1}{1+r} \right)^{t-1} \text{flow}_{i,t}(z = 0), \]

where, again, \( \text{flow}_{i,t}(z = 0) \) is the realized earnings path for the individual in question. We then compute the mean over employed persons on Day 1 to obtain \( \bar{E}(\text{Earnings, Day 1}) \) for each aggregate path. Thus, we have one value of \( \bar{E}(\text{Earnings, Day 1}) \) and 5,000 values of \( \bar{U}(\text{Earnings, Day 1}) \) for each aggregate path.

Lastly, we compute a realized present value earnings loss measure for each individual in a manner analogous to step 6 above, obtaining

\[ R_{\text{Earn \_ Loss}} = 100 \left[ \frac{\bar{E}(\text{Earnings, Day 1}) - \bar{U}(\text{Earnings, Day 1})}{\bar{E}(\text{Earnings, Day 1})} \right]. \]

Table 4 reports statistics for the distribution of individual-level values of \( R_{\text{Earn \_ Loss}} \) for all aggregate paths (Panel B) and subsets of aggregate paths (Panels C and D).

2. Model of Burgess and Turon (Table 5)

As before, we calculate present value income losses due to job loss as a percent of employment asset values. We also calculate present value earnings losses over a 20-year horizon, expressed as a percent of present value earnings over 20 years.
Before describing the simulation details, it will be helpful to define the objects we calculate. Let \( f^p(\varepsilon) \) denote the density function of filled jobs in aggregate productivity state \( p \), where \( \varepsilon \) is the idiosyncratic productivity value, and let \( F^p \) be the corresponding distribution function. Following Burgess and Turon, we ignore the short-term dynamics of \( f^p(\varepsilon) \) for a given aggregate productivity state and, in solving the model, calculate the “stationary” distribution of filled jobs that prevails when aggregate productivity remains constant for a period of time. Employers and workers know the stochastic processes governing aggregate and idiosyncratic shocks and how the distribution \( F^p \) shifts in response to aggregate productivity. They account for the stochastic elements of the environment when making choices about job creation, recruitment, search and wages. Burgess and Turon show that wages can be expressed as a function of \( p \) and \( \varepsilon \).

Let \( E^p(\varepsilon;z,T) \) denote the present value of expected future income or earnings flows for a worker currently employed in a job with idiosyncratic productivity \( \varepsilon \) when the aggregate state is \( p \). Evaluating \( E^p(\varepsilon;z,T) \) at \( z = \) income value of leisure and \( T = \infty \) yields the expected present value of income. Evaluating at \( z=0 \) and \( T=80 \) quarters yields the expected present value of earnings over a 20-year horizon. Similarly, \( U^p(z,T) \) is the present value of expected future income or earnings for an unemployed worker in aggregate state \( p \).

Panel A in Table 5 reports present value loss measures in the Good, Middle and Bad aggregate states. Specifically,

\[
\text{Panel A: } \int \left\{ \left[ \frac{E^p(\varepsilon;z,T) - U^p(z,T)}{E^p(\varepsilon;z,T)} \right] f^p(\varepsilon) \right\} d\varepsilon,
\]

where \( p \) indexes the aggregate state, and we evaluate \( z \) and \( T \) to recover the present value loss of income or earnings, as discussed above. For the income loss calculations, the
relevant \( E^p(\varepsilon) \) and \( U^p \) objects are value functions. For the earnings loss calculations, we construct the relevant \( E^p(\varepsilon) \) and \( U^p \) objects by simulating aggregate and individual-level earnings paths as described below. The Panel A calculation can be interpreted as the present value loss due to job loss relative to the worker’s pre-displacement situation (own past) and relative to the situation for workers who remain employed in a job with the same value of \( \varepsilon \) as the pre-displacement job (control group). These two benchmarks – own past and control group – yield the same loss calculation in this case.

Rows C through N in Table 5 report present value income and earnings losses for workers who lose jobs in the wake of a negative shock to aggregate productivity. Job destruction and job loss now arise because of (sufficiently) negative idiosyncratic productivity shocks, as in Panel A, and because the negative aggregate shock generates a burst of job destruction at the lower end of the match productivity distribution. We describe the present value calculations for the Good(G) to Middle(M) transition; i.e., in the wake of a shock that shifts aggregate productivity from Good to Middle. Analogous calculations hold for the Good→Bad and Middle→Bad transitions. The present value loss expressions for the Good→Middle transition are given by

Panel C and I:  
\[
\int \left[ \frac{E^G(\varepsilon; z, T) - U^M(z, T)}{E^G(\varepsilon; z, T)} \right] f^G(\varepsilon) d\varepsilon,
\]

Panel D and J:  
\[
\int_{R(G)}^{R(M)} \left\{ \frac{E^G(\varepsilon; z, T) - U^M(z, T)}{E^G(\varepsilon; z, T)} \right\} f^G(\varepsilon) d\varepsilon, \text{ and}
\]

Panel F and L:  
\[
\int \left[ \frac{E^M(\varepsilon; z, T) - U^M(z, T)}{E^M(\varepsilon; z, T)} \right] f^M(\varepsilon) d\varepsilon,
\]

where \( R(p) \) is the job destruction threshold in aggregate productivity state \( p \).
The expression for Panels C and I gives the mean PV loss in the Middle aggregate state relative to own past PV positions in the Good state for workers who lose jobs due to idiosyncratic shocks. The expression for Panels D and J gives the mean PV loss for workers who become unemployed in the burst of job destruction triggered by the aggregate productivity transition from Good to Middle. This negative aggregate shock destroys all jobs with \( e \in [R(G), R(M)] \). Panels D and J express the PV loss relative to the worker's own past situation in the Good aggregate state. The expressions for Panels F and L give the mean PV loss for job-losing workers relative to control groups of workers who remain employed in the new Middle state. The loss expression in the Good→Middle transition for Panels F and L is identical to the loss expression in the Middle state for Panel A.\(^1\) Because all workers with \( e \in [R(G), R(M)] \) lose jobs when the economy transitions from Good to Middle, Panels G and M report zero losses for these workers relative to controls. Finally, Panels E, H, K and N report inflow-weighted averages of PV earnings losses due to the two types of job destruction shocks – negative aggregate shocks and sufficiently negative idiosyncratic shocks. At the quarterly frequency and chosen calibration, idiosyncratic shocks drive most of the job-loss events.

The simulations for the earnings loss calculations proceed as follows:

1. Set the initial aggregate state to Good, Middle or Bad.
2. Draw 2,000 aggregate paths using the transition matrix for \( p \). Let each aggregate path proceed for 80 quarters (20 years). Calculate the implied paths for the distribution function \( F^G(e) \), wage function \( w(p, e) \), and job-finding probability.

\(^1\) We integrate with respect to \( f^M(e) \) in Panels F and L rather than \( f^G(e) \), but that matters little for the results.
3. Partition \([-\sigma, \sigma]\), the range of possible productivity values, into 200 subintervals of equal length. In the first quarter of each aggregate path, choose 1,000 unemployed persons and 100 employed persons per subinterval in the support of \(F^p(\varepsilon)\). The support of \(F^p(\varepsilon)\) covers at least 150 subintervals for each aggregate state.

4. Follow the initially employed and initially unemployed persons forward in time for the 80-quarter duration of each aggregate path. Track each person’s realized earnings path given optimal search and allowing for the stochastic arrival of job opportunities when searching and idiosyncratic productivity shocks when employed. Track and store each person’s realized earnings path, where earnings equal \(w(p, \varepsilon)\) when employed and 0 when unemployed.

5. Consider all simulated individual outcomes along a given aggregate simulation path. Calculate the realized PV of earnings for each initially unemployed and each initially employed person living on that aggregate path. Compute the mean PV over initially unemployed persons to obtain \(U^p(0, 80)\) and the mean by subinterval to obtain \(E^p(\varepsilon; 0, 80)\). Plug these objects into the integral expressions above to obtain the desired PV earnings loss expression for the given aggregate path.

6. Repeat Step 5 for all aggregate paths and compute the simple mean of the PV loss expressions to obtain the results reported in Table 5.

As remarked in the main text, the calibration used for Table 5 departs from that of Burgess and Turon to obtain job-finding rates in line with U.S. experience in recent decades. For comparison purposes, Table B1 below reports results for a version of Table 5 based on the calibration of Burgess and Turon. As indicated by the entries in Panel B, the
Burgess-Turon calibration involves much lower job-finding rates than the ones considered in Table 5. As a result, the PV income and earnings losses associated with job loss are substantially larger in the Burgess-Turon calibration.

Section 5.C in the main text also reports the average difference between the pre-displacement wage and the wage on the first post-displacement job for persons who lose jobs due to idiosyncratic shocks. We calculate this statistic as follows. For initially unemployed persons in Step 4 above, store the wage in their first post-displacement job. Compute the mean of this wage over all aggregate and individual-level paths, and call it \( \bar{w}_i^p \). The wage-change statistic we report in the text is

\[
1 - \int \left[ \bar{w}_i^p / w(p,e) \right] f^p(e) \, d\epsilon.
\]

Figure B1 shows the wage function, the density of all filled jobs, and the density of first jobs for workers who exit unemployment after losing their jobs in the model of Burgess and Turon. The figure is constructed for the Good aggregate state using the same calibration as Table 5 in the main text. Wages in filled jobs vary from about 0.79 to 1.16. As seen by a comparison between the dashed and solid red lines, the distribution of filled jobs for recent job losers is more concentrated at the low end of the wage distribution than the distribution of all filled jobs. This comparison illustrates the job ladder in the model: Following a job loss event, newly reemployed workers tend to start near the bottom of the job ladder and to move up the ladder over time through search on the job.
Table B1. Present Value Losses Due to Job Loss in the Model of Burgess and Turon with their Calibration

| Present Value Losses, Percent of Employment Asset Value for Income Losses and Percent of Present Value Earnings Over a 20-Year Horizon for Earnings Losses |
|---|---|---|
| **Aggregate State** | **Good** | **Middle** | **Bad** |
| A. Mean PV Loss Due to Idiosyncratic Shocks that Result in Job Loss | Income | 0.62 | 0.58 | 0.53 |
| | Earnings | 4.38 | 4.68 | 4.98 |
| B. Quarterly (Monthly) Job Finding Rate | | 39.4 (15.4) | 35.3 (13.5) | 31.5 (11.9) |

| Present Value Income Losses |
|---|---|---|
| **Aggregate State Transition** | **Good→Middle** | **Middle→Bad** | **Good→Bad** |
| C. Mean Loss Due to Idiosyncratic Shocks that Result in Job Loss, Comparison to Own Past | | 0.84 | 0.77 | 1.04 |
| D. Mean Loss Due to Aggregate Shock that Results in Job Loss, Comparison to Own Past | | 0.23 | 0.21 | 0.43 |
| E. Inflow-Weighted Average of Rows C and D | | 0.78 | 0.72 | 0.94 |
| F. Mean Loss Due to Idiosyncratic Shocks that Result in Job Loss, Comparison to Control Group | | 0.58 | 0.53 | 0.53 |
| G. Mean Loss Due to Aggregate Shock that Results in Job Loss, Comparison to Control Group | | 0 | 0 | 0 |
| H. Inflow-Weighted Average of Rows F and G | | 0.52 | 0.48 | 0.44 |

| Present Value Earnings Losses |
|---|---|---|
| I. Mean Loss Due to Idiosyncratic Shocks that Result in Job Loss, Comparison to Own Past | | 5.44 | 5.80 | 6.09 |
| J. Mean Loss Due to Aggregate Shock that Results in Job Loss, Comparison to Own Past | | 4.48 | 5.10 | 5.23 |
| K. Inflow-Weighted Average of Rows I and J | | 5.34 | 5.73 | 5.95 |
| L. Mean Loss Due to Idiosyncratic Shocks that Result in Job Loss, Comparison to Control Group | | 4.68 | 4.98 | 4.98 |
| M. Mean Loss Due to Aggregate Shock that Results in Job Loss, Comparison to Control Group | | 0 | 0 | 0 |
| N. Inflow-Weighted Average of Rows L and M | | 4.21 | 4.51 | 4.14 |

| Average Relative Wage Loss Due to Idiosyncratic Shocks That Result in Job Loss | | 5.17 | 4.00 | 4.58 |

Notes: The calculations in this table follow those of Table 5 in the main text. Here, we use the calibration of Burgess and Turon, which involves substantially smaller job-finding rates.
Figure B1. Wage Function and Density of Filled Jobs in the Model of Burgess and Turon for the Table 5 Calibration

Notes:
1. The bold black line shows the wage as a function of the idiosyncratic productivity value, $\varepsilon$, in the Good aggregate state.
2. The solid red line shows the density function of filled jobs in the Good aggregate state.
3. The dashed line shows the density function of first post-displacement jobs for workers leaving unemployment after losing their former jobs.
